1 INTRODUCTION

Calmodulin (CaM) was discovered as an activator of cyclic nucleotide phosphodiesterase in brain by Cheung¹ and by Kakiuchi and Yamazaki² in 1970. Since then, it has become clear that CaM is a ubiquitous intracellular calcium receptor present in eukaryotic cells and that its structure has been highly conserved during evolution.³ The amino acid and gene sequences of CaM from various species have been determined.⁴⁻⁶ Figure 1 shows the amino acid sequence of bovine brain CaM.⁴ The molecular weight of CaM is ca. 16 700. The amino terminal is acetylated and lysine-115 is trimethylated at the ϵ position. CaM consists of four repeated sequences of about 35 amino acid residues, each of which forms a helix-loop-helix Ca^{2+} -binding motif of the EF-hand type, first discovered in parvalbumin by Kretsinger and co-workers.⁷ The biophysical properties of CaM have been extensively studied (for reviews, see Cohen and Klee⁵). CaM is an acidic ($\text{pI} = 4.3$) and heat stable protein which binds four Ca^{2+} ions. The four Ca^{2+} -binding motifs can be classified into the high affinity sites III and IV in the C-terminal region ($K_d \approx 10^{-6} \text{ M}$) and the low affinity sites I and II in the N-terminal region ($K_d \approx 10^{-5} \text{ M}$).⁸

A number of enzymes and proteins have been reported to date to be stimulated by CaM.⁴ These include myosin light chain kinase (MLCK), CaM kinase II, phosphorylase kinase, calcineurin, myristoylated alanine-rich C kinase substrate (MARCKS), and many others (for reviews, see Cohen and Klee⁵ and Crivici and Ikura⁶). Thus, CaM plays a role as a multifunctional activator or regulator in various Ca²⁺-dependent cellular processes. CaM-binding regions in many target enzymes and proteins have been mapped. These regions are generally small (14–27 amino acid residues) and rich in basic and hydrophobic residues. Most of the CaM-binding sequences identified so far appear to have a propensity for helix formation. A number of naturally occurring peptides are also known to bind CaM in a Ca²⁺-dependent manner.⁹ These peptides include insect venom peptides such as mastoparans and melittin, and certain hormones and opioids such as ACTH, VIP, glucagon, and substance P. In addition, phenothiazines and other hydrophobic drugs including trifluoperazine (TFP), chlorpromazine, and W-7, bind CaM and inhibit the CaM-mediated activation of enzymes.¹⁰ Proteolytic fragments and synthetic peptides comprising the CaM-binding regions of target proteins, as well as the insect and hormone peptides and

Figure 1 The amino acid sequence of bovine brain calmodulin⁴
[Courtesy of C. B. Klee]

the hydrophobic drugs, have been extensively used to study the structural and biochemical properties of the interaction of CaM with targets.

The crystal structures of Ca^{2+} -loaded CaM were reported by Babu et al.¹¹ in 1985 and by Kretsinger et al.¹² in 1986. The structures have an unusual dumbbell shape [Figure 2(a)] in which the N- and C-terminal globular domains are connected by a long α -helix. The length of the molecule is about 65 Å, with each lobe having approximate dimensions of $25 \times 20 \times 20$ Å.³ Each domain possesses a hydrophobic patch, which is considered to be responsible for target binding. Similar structural features were found in the crystal structure of a homologous Ca^{2+} -binding protein, skeletal muscle troponin C¹³ (see *Calcium-Binding Proteins* and *Muscle Proteins*). In 1992, an NMR structure of CaM complexed with a 26-residue CaM-binding peptide derived from skeletal muscle MLCK was determined¹⁴ [Figure 2(b)]. Subsequently, a crystal structure of CaM complexed with a smooth muscle MLCK peptide was also solved at 2.4 Å. More recently, a crystal structure of CaM complexed with a CaM kinase II peptide has been reported.¹⁶

Detailed mechanisms by which CaM regulates the activity of target enzymes and proteins are still not yet fully understood even for a single case. Nevertheless, NMR spectroscopy has contributed tremendously to our understanding of the structural basis of the action of CaM in the context of interactions with

Ca^{2+} , and peptides and drugs. In the following discussion NMR studies on CaM reported during the period of 1979–93 will be summarized.

2 INTERACTIONS WITH METAL IONS AND DRUGS

The first 250- and 360-MHz ^1H NMR spectra of bovine brain CaM were reported by Seamon^{17,18} in 1979 and 1980, who demonstrated that dramatic Ca^{2+} -dependent spectral changes could be monitored by ^1H NMR. Aromatic proton resonances of Tyr-99, His-107, and Tyr-138, and a unique trimethyl group of ϵ -trimethylated Lys-115 were identified. Klevit et al.¹⁹ and Krebs and Carafoli²⁰ studied the interaction of bovine brain CaM with TFP using ^1H NMR. Shimizu et al.^{21,22}

used ^{19}F NMR to study the interactions of porcine brain and *Tetraphymena pyriformis* CaM with TFP. All these studies indicate that one CaM molecule binds two TFP molecules.

More detailed assignments for aromatic ring and methyl protons in scallop testis CaM were reported by Ikura et al.²³ in 1983. Using those resonance assignments, Ca^{2+} -induced conformational changes have been examined.²⁴ Figure 3 illustrates Ca^{2+} -induced changes in the aromatic region of the ^1H NMR spectra. The results show that many resonances C-terminal domain (Phe-99, His-107, trimethyl Lys-115, and Tyr-138) are shifted in an early stage of Ca^{2+} titration (0–2 mol Ca^{2+} per mol of CaM), thus concluding that the C-terminal domain contains the high affinity sites for Ca^{2+} . Forsén and co-workers independently reached the same conclusion from ^{43}Ca and ^{113}Cd NMR studies^{25,26} using two tryptic fragments

Figure 2 Ribbon diagram representations of (a) Ca^{2+} -CaM¹¹ and (b) the Ca^{2+} -CaM-M13 complex¹⁴ as generated by the program ribbons. The CaM N-terminal domain is shown in blue and the C-terminal domain in red. In Figure 2(b), the structure is viewed parallel to the M13 peptide helix axis

of CaM (TR₁C, fragment 1–75; TR₂C, fragment 78–148). These half-fragments were found to be extremely useful for NMR studies of CaM. In 1984, ¹H NMR studies on the half-fragments were reported by three groups^{27–30} almost at the same time. Two uniquely low-frequency shifted ring proton resonances at 6.46 and 6.50 ppm of apo-CaM were assigned to phenylalanines in the N-terminal domain. All these studies provided further evidence for the order of Ca^{2+} binding to four sites in CaM. Together with ⁴³Ca and ¹¹³Cd NMR^{25,26} and other biophysical studies,^{4,5,8} it became clear that the two tryptic half-fragments retain the conformations which they assume in whole CaM. The property was shown for both the Ca^{2+} -free and Ca^{2+} -bound forms.

Because of the complexity of the ¹H NMR spectra of whole CaM, several groups used the tryptic half-fragments to elucidate the structural details of CaM. In 1984, Aulabaugh et al.³¹ applied 2D ¹H NMR at 600 MHz to fragment TR₂C in the absence of Ca^{2+} and obtained assignments for many side-chain proton resonances to particular amino acid types. In 1985, Ikura et al.³² applied 2D ¹H NMR techniques to the TR₂C fragment both in the presence and the absence of Ca^{2+} , and obtained about 30% backbone and side-chain proton assignments in each state using the sequential assignment

procedure proposed by Wüthrich and co-workers (see *Biological Macromolecules: Structure Determination in Solution and Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*). Extremely high-frequency shifted amide proton resonances (10.0–11.0 ppm) were assigned to the glycine residues at the fifth position of the Ca^{2+} -binding loops. These uniquely shifted glycine amide resonances were further characterized using both TR₁C and TR₂C fragments.³³ Such large shifts of the amide protons of this conserved glycine residues in EF-hand Ca^{2+} -binding loops were also found in troponin C³⁴ and calbindin³⁵ (see *Calcium-Binding Proteins*), suggesting that this feature is universal among the members of the EF-hand superfamily. Hoffman and Klevit³⁶ reported 2D ¹H NMR analysis of the Ca^{2+} -free TR₁C fragment in the absence of Ca^{2+} , indicating hydrophobic contacts between Phe-16 and Val-35 which are absent in the Ca^{2+} -bound form of the crystal structure.^{11,12} More recently, Finn et al.³⁷ obtained the complete backbone ¹H resonance assignments of the Ca^{2+} -free TRC fragment, indicating that the Ca^{2+} -free state retains the helix-loop-helix secondary structure similar to that observed in the Ca^{2+} -bound form.^{11,12,38}

Figure 3 The aromatic region of the 400 MHz ^1H NMR spectra of scallop testis calmodulin at various Ca^{2+} concentrations. (Reproduced by permission of the American Chemical Society from Ikura et al.²⁴)

Several different NMR techniques were used to study the kinetics of Ca^{2+} binding to CaM and its fragments. Calcium-43 and ^{113}Cd NMR studies^{25,26} indicate that the resonances from metal ions bound to sites III and IV show much slower exchange on the NMR timescale than those from metal ions bound to sites I and II. ^1H NMR saturation transfer and spectral simulation methods were employed to obtain the exchange rate constants and activation parameters between Ca^{2+} -free and Ca^{2+} -bound forms of two half-fragments.³⁹ Two distinct rate constants of $3\text{--}10\text{ s}^{-1}$ and $300\text{--}500\text{ s}^{-1}$ were found at 22°C for the C-terminal and the N-terminal fragments, respectively. All these results confirm the identification of sites III and IV as being the high affinity sites.

Starovasnik et al.⁴⁰ studied the Ca^{2+} binding and structural properties of CaM from the yeast *Saccharomyces cerevisiae* using flow dialysis and ^1H NMR. The amino acid sequence of yeast CaM is 60% identical to that of vertebrate CaM, whereas all known vertebrate CaM sequences are totally identical. The results indicate that, unlike vertebrate CaM, yeast CaM binds only three Ca^{2+} ions and that all three sites exhibit slow-exchange behavior upon Ca^{2+} binding. Thermal denaturation properties of yeast CaM as well as of its half-fragments were also studied. Starovasnik et al.⁴¹ studied a series of four site-directed mutants using the same techniques, demonstrating interactions between the Ca^{2+} -binding sites in CaM.

Vogel and co-workers have extensively studied lysine residues in CaM using ^1H and ^{13}C NMR. The pK_a values of *N*-dimethylated lysine residues were obtained both in apo and Ca^{2+} -bound forms, as well as in a complex with a 22-residue peptide comprising the CaM-binding region of skeletal muscle

MLCK.^{42,43} Zhang et al.⁴⁴ applied ^{14}N NMR to ϵ -trimethyl Lys-115 in both vertebrate and yeast CaMs. The ϵ -trimethyl group of this posttranslated lysine gives rise to a sharp ^{14}N NMR resonance because of its unique tetrahedral symmetry. Selenium-77 NMR was used to study the microenvironments of the nine methionine residues in CaM, all of which were biosynthetically substituted with selenomethionine.⁴⁵

3 CALCIUM-CALMODULIN COMPLEX

During the period 1989–93, CaM was extensively used by Bax's group at the NIH to develop multidimensional heteronuclear MR methods (see *Multidimensional Spectroscopy: Concepts, and Three- and Four-Dimensional Heteronuclear Magnetic Resonance*). This methodology requires isotope enrichment of proteins with ^{15}N and ^{13}C . Uniformly ^{15}N - and ^{13}C -labeled CaM was obtained using an *E. coli* expression system.⁴⁶ Figure 4 shows a ^1H – ^{15}N heteronuclear single quantum coherence (HSQC) spectrum of Ca^{2+} -loaded recombinant CaM labeled uniformly with ^{15}N , illustrating that a high-quality ^1H – ^{15}N shift correlation spectrum can be obtained at 1 mM protein concentration. Ikura et al.^{38,47} reported complete backbone and side-chain ^1H , ^{13}C , and ^{15}N assignments of Ca^{2+} -loaded recombinant *Drosophila* CaM using a series of triple- and double-resonance 3D and 4D experiments. The secondary structure in solution was then characterized using NOE, $^3J_{\text{NH}\alpha}$ coupling constants, and ^{13}C chemical shift data.³⁸ These results confirm the crystal structure^{11,12} in that both the N- and C-terminal globular domains assume a pair of the EF-hand type helix–loop–helix motifs. However, the central helix portion (residues 65–92), found in the crystal structure, appears to contain a nonhelical region at residues 78–81 in solution. Nitrogen-15 relaxation studies reported by Barbato et al.⁴⁸ further indicate that this nonhelical portion has considerable flexibility, consistent with other studies using solution techniques such as small angle X-ray or neutron scattering.⁴⁹ The ^{15}N relaxation studies⁴⁸ (see *Protein Dynamics from NMR Relaxation*) provide additional interesting insights into the structure and dynamics of Ca^{2+} –CaM. The rotational correlation times obtained for the N- and C-terminal domain (7.1 ns and 6.3 ns, respectively) do not reflect the overall motion of a 16.7 kDa protein, but rather correspond to that of a smaller protein (ca. 12 kDa). Further, the correlation times for the individual amide bond vectors vary to a much lesser degree than predicted by hydrodynamic calculations for rigid dumb-bell models. These results indicate that the two domains move independently in solution.

4 CALCIUM-CALMODULIN-PEPTIDE TERNARY COMPLEXES

In 1985, Klevit et al.⁵⁰ using ^1H NMR studied the interaction of CaM with a 26-residue synthetic peptide (known as M13) comprising the CaM-binding domain of skeletal muscle myosin light chain kinase. These data indicate that both the N- and C-terminal domains must participate in the interaction with the M13 peptide. The ^{113}Cd NMR studies of mastoparan binding to Cd_4CaM have shown that both the N- and C-terminal domains undergo conformational

Figure 4 The 500 MHz ^1H - ^{15}N HSQC shift correlation spectrum of *Xenopus laevis* calmodulin. The spectrum was recorded using a pulse sequence combined with the pulse field gradient technique described by Kay et al.⁶⁶ The full backbone amide assignment of *Xenopus* calmodulin is available from the author

changes upon binding of the peptide (see **Calcium-Binding Proteins**). Seeholzer et al.⁵¹ also used ¹H NMR to study the interaction of melittin with [¹H]- and [²H]-CaM, suggesting that melittin assumes an α -helical conformation upon binding CaM, consistent with earlier conclusions based on circular dichroism spectra. Yazawa et al.,⁵² using the ¹H NMR signal of His-107, showed that in the presence of M13 the Ca²⁺-dependent conformational change becomes completely cooperative between the N- and C-terminal domains. Ikura et al.⁵³ studied the Cd²⁺ dependence of the interactions of CaM with M13 and mastoparan using ¹¹³Cd NMR, supporting the notion of the higher cooperativity of metal binding in the presence of these peptides. Ohki et al.^{54,55} studied the interaction of mastoparan with CaM under various solution conditions using ¹H NMR. It was shown that the N-terminal domain may interact with a second mastoparan molecule with a lower affinity, and that Mg²⁺ reduces the cooperative Ca²⁺ binding to CaM in the presence of mastoparan.

In 1991, Ikura et al.⁵⁶ completed ¹H, ¹³C, and ¹⁵N backbone assignments of Ca²⁺-CaM complexed with M13 by using multidimensional heteronuclear MR methods. Proton assignments of M13 in the complex were also obtained using ¹⁵N/¹³C-filtered techniques⁵⁷ (see **Half-Filter Experiments: Proton-Carbon-13**). Based on these assignments, the three-dimensional NMR structure of the Ca²⁺-CaM-M13 ternary complex was determined.¹⁴ Figure 2(b) shows a schematic ribbon model of the restrained minimized mean structure. A striking difference in conformation can be seen as compared with the crystal structure of Ca²⁺-CaM¹¹ [Figure 2(a)]. The N- and C-terminal domains of CaM (residues 6–73 and 83–146) remain essentially unchanged upon complexation. The long central helix, (residues 65–93), however, which connects the two domains in the crystal structure of Ca²⁺-CaM [Figure 4(a)], is disrupted into two helices connected by a long flexible loop (residues 74–82), thereby enabling the two domains to clamp residues 3–21 of the bound peptide which adopt a helical conformation. Key residues of the peptide are Trp-4 and Phe-17, which serve to anchor the N- and C-terminal halves of the peptide to the C- and N-terminal domains of CaM, respectively. This characteristic structure of Ca²⁺-CaM complexed with the M13 peptide was confirmed by a crystallographic study on Ca²⁺-CaM complexed with a similar peptide derived from smooth muscle MLCK.¹⁵ Based on the knowledge of the structural features of these Ca²⁺-CaM-peptide complexes, Prumb et al.⁵⁸ produced a hybrid CaM-peptide molecule and characterized the structural and Ca²⁺-binding properties using ¹H–¹⁵N HSQC and flow dialysis experiments.

Roth et al.^{59,60} revealed the secondary structure of a 19-residue smooth muscle MLCK peptide and CaM in their complex using heteronuclear multidimensional NMR techniques. Most of the backbone amide nitrogen nuclei in the MLCK peptide were labeled with ¹⁵N, which allowed the characterization of the α -helix structure of the peptide. Precheur et al.⁶¹ also used a similar labeling technique on a 17-residue model peptide proposed by DeGrado et al.,⁶² and showed a stable α -helical structure in the N-terminal 11 residues of the complex. Zhang et al.,^{63,64} using 2D ¹H NMR, studied three synthetic CaM binding peptides which are derived from skeletal muscle MLCK, rat cerebellar nitric oxide synthase, and smooth muscle caldesmon. The MLCK⁶³ and caldesmon⁶⁴ peptides were found to assume an α -helical conformation in an aqueous trifluoroethanol mixture

(75%/25%) The nitric oxide synthase peptide⁶⁶ also adopts an α -helical structure in aqueous solution at pH 5.5 and 5 °C.

In summary, CaM has provided an excellent example of the power of the high-resolution multinuclear magnetic resonance approach. Various NMR studies have provided valuable information on the structural and physical properties of CaM as a Ca²⁺-sensitive molecular switch in cells. Yet, further studies have to come in order to elucidate secrets involved in multitarget recognition of this amazing molecule.

1 INTRODUCTION

The expansion of glycobiology into the realm of the structure–function relationships of carbohydrates is strongly dependent upon advances in technology. Unquestionably, nuclear magnetic resonance (NMR) spectroscopy has made the most significant impact on structural studies of oligosaccharides and glycoconjugates. While researchers in the past (1960–84) concerned themselves in the first place with the study of primary carbohydrate structures, NMR spectroscopy has recently (1985–94) reached a level of sophistication which allows the conformational analysis of oligosaccharides, glycopeptides, and glycolipids in solution. This article briefly summarizes the early days of carbohydrate NMR, reviews the application of current NMR spectroscopic techniques to the structural and conformational characterization of oligosaccharides from glycoproteins and glycolipids, and ends with a discussion of some questions about carbohydrate structure, dynamics, and function that can be addressed by NMR in the near future.

2 CARBOHYDRATES AND GLYCOCONJUGATES: STRUCTURE AND FUNCTION

The carbohydrate moieties of glycoconjugates, i.e., glycoproteins and glycolipids, generally have complex structures featuring highly varied chemical functionalities. These oligosaccharide chains, varying in size from two to 20 or more residues, are composed of neutral monosaccharides such as d-mannose (Man) and d-galactose (Gal), amino sugars such as *N*-acetyl-d-glucosamine (GlcNAc) and *N*-acetyl-d-galactosamine (GalNAc), the C-6-deoxy sugar l-fucose (Fuc), and the nine-carbon-atom acidic sugars of the sialic acid family of which *N*-acetylneuraminic acid (Neu5Ac) is the most commonly found representative (for structures, see Figure 1). In glycoproteins, these oligosaccharide chains are covalently

attached to the side chains of specific amino acids such as Asn, Ser, and Thr. Glycoproteins are anchored to the outer surface of the cell's plasma membrane by either a transmembrane peptide fragment or by a phosphatidyl-inositol anchoring lipid. Complex carbohydrate chains similar to those of glycoproteins may also be found attached to lipids similarly inserted in the plasma membrane where they present the hydrophilic carbohydrate chain to the extracellular environment (Figure 1).

Because of their structural diversity, glycoconjugate oligosaccharides are potentially rich sources of biological information. Although the precise function of the carbohydrate chains of glycoproteins and glycolipids is not fully understood, it has been proposed that they are informational macromolecules with signals encoded in their structure that are crucial to the biological functions of the cells carrying them.¹ As this information apparently relates to intercellular communication and control of cellular growth and differentiation, it is possible that complex carbohydrates play an important role in such important processes as developmental biology and tumor metastasis. Areas of focus in current glycobiology research include the importance of oligosaccharides to immune mechanisms, the association of certain structural changes with diseases such as malignant cancer growth and rheumatoid arthritis, and the potential for the development of novel therapeutic strategies [recombinant glycoproteins such as erythropoietin and tissue plasminogen activator are already in widespread clinical use for the treatment of anemia and myocardial infarction, respectively, while the glycolipid 'ganglioside GM1' (Figure 1) is administered to alleviate the symptoms of cholera].

From a structure–function point of view, the 20th century has come full circle: Landsteiner's discovery, around 1900, of the ABH blood group antigens inspired structural studies that culminated in the identification of the antigens as tri- and tetrasaccharide epitopes at the nonreducing termini of the glycoprotein and glycolipid carbohydrate chains found on the cell surface of erythrocytes and many other mammalian tissues (Figure 1). Landsteiner's pioneering work sparked investigations into the involvement of carbohydrates in immune protection and in graft versus host reactions in blood transfusions and other organ transplants. The presence of sialic acid on erythrocyte surfaces proved to be a necessary requirement for their infection by the influenza virus. Malignant tumor cells were found to exhibit certain tumor-associated antigens (TAA), carbohydrate sequences not found on membrane glycoproteins and glycolipids of normal cells. TAA-like epitopes were discovered on cell surfaces in the early stages of embryonic development (hence, they are known as onco-fetal antigens).^{2–4} Around 1990, the discovery and identification of sialylated Lewis blood group carbohydrates (sLe^a and sLe^x, Figure 1) as ligands for selectins (cell adhesion molecules)^{5,6} added the latest exciting chapter to the involvement of oligosaccharides in an important biological process, in this case endothelial leukocyte adhesion being the key to inflammation.

From the beginning it was understood that an insight into the biological and physicochemical functions of complex carbohydrates at the molecular level would require a precise knowledge of the primary and secondary structures of these often highly branched polymers with their intriguing blend of segmental rigidity and flexibility. The complete structural characterization of complex carbohydrates involves

Figure 1 (a) Schematic representation of a cell's plasma membrane with an emphasis on the glycoprotein and glycolipid carbohydrate chains, the cell's communication organelles. (b) Primary structures of some commonly found glycoprotein and glycolipid carbohydrate chains. Represented from top to bottom: a diantennary *N*-type glycoprotein oligosaccharide, an *O*-type glycoprotein tetrasaccharide, and the monosialo and disialo gangliosides G_{M1} and G_{D1a} (Asn = l-asparagine; Ser = l-serine; Cer = ceramide, the generic name for an *N*-acylated sphingosine). (c) Structures of typical constituent monosaccharides of glycoprotein and glycolipid oligosaccharide chains (Man, Gal, GlcNAc, GalNAc, Fuc, and Neu5Ac, drawn in the α -configuration of their thermodynamically most stable pyranose ring forms). (d) Structures of selected blood group and differentiation antigens

determining (i) the type, number, and primary sequence of the constituting glycosyl residues, including the occurrence of branch points and the location of appended noncarbohydrate groups and (ii) their three-dimensional (3D) conformation(s) and dynamics in solution. Although determining the complete structure of a carbohydrate usually requires the application of a combination of chemical, enzymatic, and spectrometric methods,^{7,8} NMR spectroscopy has emerged as the single most powerful technique for the accomplishment of this task. The nuclei of predominant interest in NMR studies of carbohydrates are ^1H and ^{13}C . The natural allocation of hydrogen and carbon atoms in carbohydrate molecules lends itself to the revelation of their complete primary structure through ^1H and ^{13}C NMR analysis. Whereas the

primary structural characterization of carbohydrates relies on a combination of techniques, only one of which is NMR spectroscopy, solution conformation analysis is almost entirely the domain of NMR spectroscopy. X-ray structures of glycoconjugates are not commonly available (and if they are, carbohydrates are usually not well-defined), and molecular modeling of carbohydrates, although a hotly contested area of research, is still in its infancy and, therefore, of little help to the experimentalist to date.

The purpose of this review is to put NMR of carbohydrates and glycoconjugates in its historical perspective; not surprisingly, a chronological account shows a remarkable parallel with primary and three-dimensional structure analysis. It should be noted that NMR of carbohydrates covers a much

broader area than solution-state ^1H and ^{13}C NMR of monosaccharides, oligosaccharides, and glycoconjugates. Polysaccharides are the topic of the article by Bush (*Polysaccharides and Complex Oligosaccharides*), and ^2H NMR of glycolipids is covered in Jarrell's article (*Glycolipids*). Here we will cover neither the application of solid state NMR to carbohydrates nor touch upon ^{31}P NMR of sugar phosphates, ^{15}N NMR of amino sugars, ^{17}O NMR of carbohydrates, and NMR of X-nuclei (^{11}B , ^{119}Sn , etc.) in carbohydrate adducts (see, for example, Bush⁹). We will further limit the discussion in this article largely to pyranose ring systems. For the discussion of furanose rings and their flexibility, the reader is referred to articles by Altona (*Vicinal Coupling Constants and Conformation of Biomolecules*), Hilbers (*Nucleic Acids: Spectra, Structures, and Dynamics*), and others covering NMR of nucleic acids. Furthermore, the molecules (peptides/proteins, lipids) that serve as appended groups of carbohydrates in glycoconjugates are discussed elsewhere throughout this Encyclopedia.

3 THE PAST: PRIMARY STRUCTURE

The initial discovery of the potential value of NMR spectroscopy for carbohydrate structural and conformational analysis is described by Lemieux in his book entitled 'Explorations with Sugars: How Sweet It Was'.¹⁰ We quote:

In spite of the difficulties and shortcomings of the NMR technique [in 1955], it became evident that acetylated sugars, because of large differences in chemical shifts, were very interesting substances with which to explore the possible use of ^1H NMR spectroscopy in organic chemistry. It soon became apparent that an equatorially oriented hydrogen generally gave rise to a signal at a lower field compared with that of a chemically similar but axial hydrogen.¹¹ This discovery was very encouraging. However, the big excitement came when [...] significant improvements in resolution were made. Examination of the spectra of [...] cyclohexanol acetates firmly established that the spin-spin coupling constants for vicinal hydrogens in antiperiplanar orientation were two to three times larger than those for vicinal hydrogens in a synclinal relationship.¹² [...] The discovery provided the long-sought definitive basis for the assessment of the preferred conformations of the sugar acetates in solution. [...] The spectra of *trans,trans*- and *cis,trans*-di-*O*-methylcyclohexanol acetate, shown in Figure 2, represent the first application of NMR for the establishment of the relative configurations of chiral centers in organic compounds. Thus, the experimental foundation was laid for the Karplus relationship¹³ between the vicinal coupling constant and the torsion angle and for the use of the time-averaged coupling constants to estimate conformer populations.

The stereochemistry of a particular monosaccharide provides its signature in the ^1H NMR spectrum; the ^1H signals of most monosaccharides can readily be assigned to the appropriate (aliphatic) protons by making use of the observed chemical shifts and splitting patterns. Thus, the foundation for the identification of carbohydrates by ^1H NMR spectroscopy had been laid.

Section 3.1 below elaborates on the empirical rules that emerged from the inspection of ^1H and ^{13}C NMR spectra of monosaccharides and simple oligosaccharides of known primary structure. Sections 3.2 and 3.3 below summarize 1D ^1H NMR spectroscopy as a fingerprinting method for

Figure 2 The first application of ^1H NMR spectroscopy, at 40 MHz, for the determination of stereochemical configuration (adapted from Lemieux et al.;¹⁴ spectra reproduced with permission from the American Chemical Society). For the *cis,trans* isomer, $^3J(\text{H-1},\text{H-2}) = 3\text{ Hz}$ and $^3J(\text{H-2},\text{H-3}) = 7\text{ Hz}$ (traces a and b); for the *trans,trans* isomer, $^3J(\text{H-1},\text{H-2}) = ^3J(\text{H-2},\text{H-3}) = 7\text{ Hz}$ (traces c and d)

the characterization of the primary structure of glycoprotein and glycolipid oligosaccharide chains, respectively, and the usefulness of an empirical concept that emerged during the 1980s for the interpretation of the ^1H NMR spectrum of a glycoprotein or glycolipid carbohydrate in terms of its primary structure is outlined. Ongoing efforts aimed at computer-assisted carbohydrate NMR spectral 'interpretation' are mentioned as well. Finally, Section 3.4 takes the concepts developed in previous sections to the level of de novo primary structural elucidation of glycoconjugate carbohydrates by 1D and 2D ^1H and ^{13}C NMR spectroscopy.

3.1 Monosaccharides and Simple Oligosaccharides

As their generic name implies, carbohydrate molecules contain numerous carbon and hydrogen nuclei. It follows that the magnetically active nuclei in carbohydrates that are of practical interest to NMR spectroscopists are those of ^1H

and ^{13}C atoms. For example, each hexosyl residue [such as the galactosyl residue in Figure 3(a)] has six carbon atoms, seven hydrogens that are involved in CH linkages, and four hydrogens in OH groups. Each of these nuclei in a glycosyl residue has its own characteristic environment and, thus, its own chemical shift. For primary structural characterization of a carbohydrate by ^1H NMR spectroscopy, the observation of the aliphatic protons suffices. Observation of hydrogens in OH groups would unnecessarily complicate spectra aimed at primary structural characterization. Therefore, the carbohydrate sample is typically dissolved in D_2O (no chemical derivatization is necessary), effectively removing any OH signals from the spectrum. Chemical shifts are referenced to the methyl signal of DSS (sodium 4,4-dimethyl-4-silapentane-1-sulfonate). The ^1H NMR spectrum of an oligosaccharide is essentially a superposition of the spectra of the individual glycosyl residues which are slightly modified because of their linkages to each other. For example, the ^1H NMR spectra of typical glycoprotein Ser-linked tri- and tetrasaccharides are shown in Figures 3(b) and 3(c).¹⁵ The subspectrum of the β -galactosyl residue is recognizable in the spectra of both the linear trisaccharide and the branched tetrasaccharide. Furthermore, Figure 3(c) clearly illustrates the difference in the NMR appearance of an $\alpha(2\rightarrow3)$ - versus an $\alpha(2\rightarrow6)$ -linked sialic acid.

The following empirical 'rules' have emerged to guide the interpretation of ^1H NMR spectra of simple carbohydrates:

1. The nonanomeric ring-skeleton protons in a glycosyl residue have very similar electron densities and, thus, chemical shifts; all of their signals appear between 3 and 4 ppm (Figures 3 and 4). In the spectrum of an oligosaccharide, the signals of the nonanomeric protons partially overlap; they constitute a broad envelope of signals in the middle of the spectrum having little fine structure and, therefore, almost no readily accessible structural information. However, anomeric protons (H-1) show signals at significantly higher chemical shifts due to their neighboring glycosidic and ring oxygens. Anomeric proton doublets are typically found between δ 4.3–5.6 ppm.

2. A proton in an equatorial position at a certain carbon atom in a pyranose ring has a chemical shift ~ 0.5 ppm higher than the corresponding axial proton attached to the same carbon. Therefore, for d-residues involved in α -glycosidic linkages (H-1 equatorial), $\delta(\text{H-1}) \sim 4.9\text{--}5.6$ ppm, while for β -anomeric linkages (H-1 axial), $\delta(\text{H-1}) \sim 4.3\text{--}4.7$ ppm. For carbohydrates in D_2O at ambient temperature, these positions correspond to the near left and right of the HDO signal (at $\delta \sim 4.80$), respectively. Further illustrating this rule, the equatorial Man H-2 signals are typically found ~ 0.5 ppm further to the left than the axial GlcNAc or Gal H-2 signals (Figure 4). Also, Gal H-4 protons resonate ~ 0.5 ppm further to the left than GlcNAc H-4 protons (compare Figure 3).

3. Each anomeric proton, by virtue of its $^3J(\text{H,H})$ scalar coupling to H-2, resonates as a doublet. The magnitude of the coupling constant reflects the relative orientation of neighboring protons. The coupling constant $^3J(\text{H-1,H-2})$ for two neighboring protons (H-1 and H-2, separated from each other by three covalent bonds) that are both in axial orientation is 7–8 Hz (i.e., relatively large), while coupling constants $^3J(\text{H-1,H-2})$ between two neighboring protons, one of which is axial and the other equatorial, or between two equatorial protons, are 3–4 Hz (relatively small). Thus, the anomeric configuration of a glycosyl residue can be inferred both from

Figure 3 (a) The computer-simulated ^1H NMR spectrum of a β -linked galactopyranosyl residue in D_2O . (b) The 600 MHz ^1H NMR spectrum (D_2O , $\text{pD} = 6$, 23°C) of a linear O -type trisaccharide-alditol ($70\ \mu\text{g}$) obtained from a glycoprotein via reductive alkalineolysis.¹⁵ (c) The 600 MHz ^1H NMR spectrum (D_2O , $\text{pD} = 6$, 23°C) of an O -type tetrasaccharide-alditol ($75\ \mu\text{g}$) released from a glycoprotein via reductive alkalineolysis.¹⁵ Superscripts in NeuAc³ and NeuAc⁶ refer to the position of the linkage in which these residues are involved

Figure 4 (a) The 500 MHz ^1H NMR spectrum (D_2O , $\text{pD} = 6$, 21°C) of a typical diantennary N -type oligosaccharide side chain of a glycoprotein (250 μg , examined as oligosaccharide-alditol, obtained by N -glycanase digestion of the glycoprotein and subsequent chemical reduction). The residual HOD signal was suppressed by low-power presaturation. (b) Structural-reporter-group regions of spectrum (a). The numbers in the spectra refer to the corresponding glycosyl residues in the structure

the chemical shift and the coupling constant of its anomeric-proton signal in the ^1H NMR spectrum.

4. When a glycosyl residue has either an additional glycosyl residue or a noncarbohydrate group attached at a certain carbon position, the signal of the proton attached to this carbon tends to shift $\sim 0.2\text{--}0.5$ ppm to the left in the spectrum. Therefore, signals of nonanomeric protons that are attached to linkage sites usually appear just outside the envelope resonance of skeleton protons ($3.9 < \delta < 4.4$) (Figure 4); they become individually observable ‘structural-reporter’ signals (Section 3.2). Thus, if the nonanomeric proton signals that emerge in the region between δ 3.9 and 4.4 ppm can be assigned, linkage positions can be deduced from a ^1H NMR spectrum.

These rules are the result of the extrapolation and rationalization of numerous NMR data obtained on mono- and disaccharides of known primary structure. Noteworthy review articles on general applications of NMR to carbohydrates, developing *inter alia* the above concepts, have appeared^{2,16,17}

including one recently.¹⁸ Additionally, the scientific literature includes extensive ^1H databases of chemical shifts for mono- and small oligosaccharides.^{19,20}

The first reports on ^{13}C NMR spectroscopy of carbohydrates appeared in the late 1960s.^{21,22} It was found that the ring ^{13}C methine signals of pyranosyl residues are typically observed between 65 and 110 ppm downfield from DSS. Anomeric carbons usually resonate between 90 and 110 ppm. The magnitude of the one-bond $^1J(\text{C-1,H-1})$ coupling for the anomeric carbon atoms reflects the configuration at the anomeric center. As a rule of thumb, $^1J(\text{C-1,H-1}) \sim 170$ Hz indicates the α -anomeric configuration, whereas $^1J(\text{C-1,H-1}) \sim 160$ Hz indicates the β -anomeric configuration. The exocyclic methylene signals of monosaccharides (in CH_2OH groups) are observed at $\sim 60\text{--}70$ ppm [unless the glycosyl residue is involved in a (1 $\rightarrow$ 6) linkage]. Extensive ^{13}C databases for mono- and simple oligosaccharides are found in the literature.^{23–28} Glycosylation shifts ($\Delta\delta \sim 10$ ppm for ^{13}C at the site of substitution, $\Delta\delta = 1$ to -2 ppm for the adjacent ^{13}C atoms) are more reproducible in ^{13}C NMR than in ^1H NMR of carbohydrates. Computer-assisted interpretation of NMR spectra of carbohydrates in terms of primary sequence based solely on ^{13}C chemical shifts^{29–31} preceded that of ^1H NMR spectra.^{32–34}

3.2 Complex Oligosaccharides Related to Glycoproteins

The carbohydrate side chains of glycoproteins are amenable to high-resolution ^1H NMR spectroscopy either as glycopeptides or as free oligosaccharides. These can be obtained from the glycoprotein by enzymatic or chemical procedures.^{7,8} A typical example of a ^1H NMR spectrum of a glycoprotein-derived N -type oligosaccharide is shown in Figure 4(a). In the early 1970s, when the complete interpretation of ^1H NMR spectra of carbohydrates of this size seemed impossible, the spectrum of an oligosaccharide was regarded by the glycobiologist primarily as a fingerprint, a readily obtainable ‘identity card’ of a carbohydrate. A mere comparison of the ^1H NMR spectra of compounds (without detailed interpretation) was used to demonstrate whether they were identical and/or pure substances. Thus, at first, a 1D ^1H NMR study appeared valuable for the primary structure determination of glycoprotein carbohydrates only if the oligosaccharide had been characterized previously by ^1H NMR in conjunction with chemical and other spectrometric methods.

However, in the late 1970s the first successful attempts were made to interpret the ^1H NMR spectra of glycoprotein oligosaccharides, even when the spectra did not match exactly any of the spectra in existing databases. Using the *structural-reporter-group concept*,^{15,35,36} the spectra were interpreted in terms of (partial elements of) carbohydrate primary structure, including anomeric configurations and positions of glycosidic linkages. The crux of this concept is that it appeared sufficient to inspect only certain regions in the spectrum [see Figure 4(b)] in order to ascertain the primary structure of the glycoprotein carbohydrate from its NMR spectrum. Perceived by some in the field as ‘mystical’ or ‘voodoo NMR’, the structural-reporter-group concept is merely an extrapolation of the empirical rules listed in Section 3.1 to larger oligosaccharides. The concept ignores the crowded region in the center of the spectrum (between 3–4 ppm, see

Figure 4); only the positions and patterns of those signals that are more or less individually observable are examined. Particularly useful structural-reporter groups are (i) the anomeric (H-1) protons, (ii) the protons attached to the carbon atoms in the direct vicinity of a linkage position, (iii) the protons attached to deoxy carbon atoms and (iv) methyl protons, e.g., in *N*-acetyl groups. The structural-reporter-group regions of the spectrum in Figure 4(a) are expanded in Figure 4(b). For the interpretation of a ^1H NMR spectrum such as depicted in Figure 4, structural-reporter-group signals are cataloged by chemical shift and coupling constants; these values are then compared with literature data on similar oligosaccharides and/or glycopeptides. A highly refined set of empirical rules was developed to rationalize the effects of structural elongations, as typically found in glycoprotein oligosaccharides, on structural-reporter-group chemical shifts. For example, the structural-reporter-group concept developed rules to identify the degree of branching as well as the type of linkage and branch location of sialic acid and fucosyl residues.^{15,35,36} Several glycoprotein carbohydrate structural-reporter-group ^1H chemical shift databases are currently available for *N*-type glycopeptides and oligosaccharides^{36–38} and *O*-type oligosaccharide-alditols³⁹ in D_2O ; other noteworthy databases are also available.^{40–43} The structural-reporter-group approach continues to enjoy considerable popularity as a method for the primary structural characterization of glycoprotein and glycolipid (for gangliosides, see Section 3.3) carbohydrates by NMR spectroscopy.

An important advantage of NMR spectroscopy over other techniques used for structural analysis of carbohydrates is its nondestructive nature. Oligosaccharide and glycopeptide samples, after NMR analysis, can be recovered unimpaired and used for other analyses, biological activity tests, etc. Glycoprotein oligosaccharides with 15–20 constituent glycosyl residues have been successfully characterized by 500 MHz one-dimensional (1D) ^1H NMR spectroscopy. Also, mixtures of components with closely related structures have been analyzed successfully. The most important limitation of NMR spectroscopy lies in its relatively low level of sensitivity. At least 10 nmol of pure carbohydrate is required to record an NMR spectrum and, even at 600 MHz, heterogeneity occurring in low abundance in the sample may escape attention. NMR spectroscopy, by its very nature, may also fail to detect the presence of nonmagnetically active nuclei, e.g. the occurrence of sulfate esters, in the carbohydrate.

Until now, the most laborious part of the NMR structural analysis of carbohydrates has been spectral interpretation. Partial or even complete primary structure determination is possible from the structural-reporter-group regions of a 1D ^1H NMR spectrum only if structurally closely related compounds have been previously characterized by ^1H NMR spectroscopy. The multitude of extremely refined rules resulting from the structural-reporter-group inspection of spectra makes interpretation of spectra of novel compounds a tedious effort. Even the basically simple process of retrieving previously recorded spectra and comparing them with a newly recorded spectrum becomes a considerable task, given the exponential growth of the amount of ^1H NMR data collected on glycoprotein and glycolipid oligosaccharides from 1980 to 1994. Assistance from computers to facilitate this aspect of the method is being sought along two different lines. The use

of a computer search algorithm to compare a list of structural-reporter-group chemical shifts with those in a database appears rather straightforward. Indeed, several such computer programs have been written to assist the interpretation of glycoprotein oligosaccharide ^1H NMR spectra.^{33,34,44} A more elegant and much faster method involves the use of the entire spectrum (including the 3–4 ppm envelope region with its high information density) for pattern recognition by artificial intelligence techniques. The NMR spectrum, already available in digital format, need not be reduced to a list of chemical shifts, as is commonly done for human interpretation. Artificial neural networks (ANN) have been successfully applied for pattern recognition of NMR spectra.^{45,46} Recently, this work has been extended to include the 500 MHz ^1H NMR spectra of glycoprotein carbohydrates.⁴⁷ In the foreseeable future, NMR spectral databases will be linked to the complex carbohydrate structure database (CCSD),⁴⁸ and the neural network search algorithms will be incorporated into CarbBank. This approach will not only render much of the previously necessary laborious supporting structural analysis work superfluous for oligosaccharides already in the database, it will also allow the interpretation of spectra by the rules resulting from the structural-reporter-group concept, thus ‘automating’ empirical NMR spectral interpretation.

An unexpected but welcome development in the application of the ANN technology for the analysis of ^1H NMR spectra lies in the potential increase in sensitivity of the method by two or three orders of magnitude. For a spectrum of a given oligosaccharide with fairly good signal-to-noise ratio (S/N) already in the database (i.e., when a neural network has been trained to recognize this spectrum in terms of the associated carbohydrate structure), the oligosaccharide can be recognized again from its ^1H NMR spectrum with a 100 to 1000-fold less S/N than the original spectrum (such as would be obtainable for subnanomole amounts of carbohydrate).⁴⁷ In the very near future, the ANN technology will make NMR competitive in terms of sensitivity with any other technique in the primary structural determination of carbohydrates related to glycoproteins and glycolipids.

In principle, ^{13}C NMR spectra can also be used for the fingerprinting of glycoprotein carbohydrates.⁴⁹ The ^{13}C spectra, recorded under ^1H decoupling conditions, consist exclusively of singlets. Further favored by the large chemical shift dispersion ($\Delta\delta \sim 100$ ppm), ^{13}C NMR spectra [even for intact glycoproteins (Section 5.1)] are often characterized by high resolution. Attempts were made to develop ^{13}C chemical shift databases for glycoprotein carbohydrate chains,⁵⁰ and to derive rules for the interpretation of spectra of novel compounds based on those of observed larger or smaller related structures. However, these efforts met with little success because of the higher demands on amounts of material needed for recording spectra and the much greater ease with which the same goal of primary structure characterization was achievable by ^1H NMR spectroscopy.

3.3 Complex Oligosaccharides Related to Glycolipids

The ^1H NMR spectroscopy principles and methodology discussed in the previous section are not only valid for glycoprotein-related carbohydrates. They apply equally well to glycolipids^{51,52} and glycosyl phosphatidyl-inositol (GPI)

anchors,⁵³ polysaccharides,²⁴ and proteoglycans.⁵⁴ Here we will limit the discussion to glycolipids. Unlike glycoproteins, glycolipids are amenable to high-resolution ^1H NMR analysis in their native state; however, they cannot be investigated in aqueous solution. Solvents such as DMSO and DMF have been successfully applied, and volumes of data that are valuable for primary structural analysis have been collected over the years. Examples of ^1H NMR databases of glycolipids in DMSO are given elsewhere.^{51,55–59}

To take advantage of the massive amount of NMR data on glycoprotein-related oligosaccharides in water, the removal of the lipid by enzymatic (endoglycoceramidase) or chemical (ozonolysis) procedures is currently employed as a standard technique for allowing the glycolipid oligosaccharides to be examined under the same circumstances as glycoprotein/glycopeptide carbohydrates and free oligosaccharides [see, for example, Figure 5(b) versus Figure 5(a)].⁶⁰

3.4 De Novo Sequencing of Glycoconjugate Carbohydrates

Although useful for the primary structural analysis of carbohydrates within the closely knit framework of structures presented abundantly by Nature for glycoprotein and glycolipid oligosaccharides, collections of chemical shifts contribute little to our understanding of NMR. However, as of the early 1980s, NMR spectroscopy provides the tools necessary to determine any novel carbohydrate structure de novo, without significant help from other techniques.

When the 1D ^1H spectrum does not resemble that of a known oligosaccharide structure, a combination of multiple pulse ^1H NMR spectroscopic techniques, primarily two-dimensional (2D) COSY, TOCSY, and NOESY or

ROESY, may be applied for the de novo sequencing of the carbohydrate.^{9,55,58} provided that 20–50 nmol of pure substance (2–5-times the amount of sample mentioned for the 1D analysis) is available for the analysis. The TOCSY technique permits subspectral editing of the ^1H spectrum for each constituting glycosyl residue^{61,62} and, consequently, the virtually complete assignment of all of the multiplet patterns in the ^1H NMR spectrum (including those in the envelope region between 3–4 ppm). Subsequently, depending on the size of the oligosaccharide and the magnetic field strength of the spectrometer used, NOESY or ROESY spectra enable the inference of the glycosyl-residue sequence, including the positions of glycosidic linkages, based on the detection of through-space connectivities.⁶³

Examples of the application of this general strategy are manifold.^{18,64–68} Because of its importance, we will briefly illustrate the strategy for a novel tetrasaccharide found O-linked to Ser₆₁ in Factor IX, a serum glycoprotein involved in the human blood clotting cascade.^{69,70} Figure 6(a) shows the 1D ^1H NMR spectrum of a glycopeptide (20 nmol) obtained from human Factor IX consisting of four glycosyl residues and nine amino acids. At the start of the NMR studies, the peptide sequence was known to be Leu₅₇–Asn–Gly–Gly–Ser–Cys*–Lys–Asp–Asp₆₅ (where Cys* indicates an *S*-carboxymethylated Cys residue). Also, it was known that the carbohydrate portion of the glycopeptide contained Gal, GlcNAc, Fuc, and Neu5Ac in equimolar ratios. In order to decipher the primary sequence of the tetrasaccharide, to pinpoint the side chain of Ser₆₁ as the site of glycosylation in the peptide, and to elucidate which of the four sugar residues was involved in the linkage to Ser₆₁, the complete assignment of the ^1H NMR spectrum of the glycopeptide was required. However, not only did the presence of the nonapeptide obscure many of the saccharide ^1H signals, it was not even possible (unlike for many other glycopeptide NMR spectra) to assign any signals in the 1D spectrum of the Factor IX glycopeptide simply by inspection. Neither the usually well-resolved structural-reporter-group signals of sugar anomeric and deoxy protons nor the amino acid H- α protons were recognizable off-hand. However, 2D correlated spectroscopy (in particular, COSY and TOCSY) was successfully applied for the identification of the spin systems of the individual sugar and amino acid residues. Figure 6(b) shows the relevant portion of the TOCSY spectrum. The resulting connectivity patterns in the COSY and TOCSY spectra were assigned to sugar and amino acid residue types based on their comparison with literature data for the individual spin systems. Subspectra for the sugar residues were traced starting from their H-1 signals (found between 4.4 and 5.5 ppm) or, in the case of Neu5Ac, from the H-3ax and H-3eq protons (expected around 1.8 and 2.7 ppm, respectively; see Figure 3). The H-1,H-2 connectivities for Gal, GlcNAc, and Fuc were particularly clear in the COSY spectrum. The TOCSY subspectra through H-1 included (in addition to the H-2 signals) the Fuc H-3, Gal H-3 and H-4, and GlcNAc H-3, H-4, H-5, and H-6/6' [Figure 6(b)].

Once the chemical shifts of 80% of the sugar protons had been established, the structural-reporter-group concept (Section 3.2) enabled the assignment of the linkage configurations and partial sequence of the four residues. The combination of chemical shifts for Neu5Ac H-3ax and H-3eq

Figure 5 (a) The 500 MHz ^1H NMR spectrum (DMSO- d_6 /D $_2$ O, 98:2, v/v; 27 °C) of an intact ganglioside. (b) The 500 MHz ^1H NMR spectrum (D $_2$ O, pD = 6, 23 °C) of the oligosaccharide released from the ganglioside by endoglycoceramidase digestion⁶⁰

Figure 6 (a) The 600 MHz 1D ^1H NMR spectrum (D_2O , $\text{pD} = 7.2$, 23°C) of the Factor IX glyco-nonapeptide (~ 20 nmol).⁶⁹ (b) Regions of the 2D ^1H TOCSY (mixing time 108 ms) and (c) ROESY (mixing time 200 ms) spectra of Factor IX glyco-nonapeptide. The sequence of the structural entities Gal β (1 $\rightarrow$ 4)GlcNAc, GlcNAc β (1 $\rightarrow$ 3)Fuc, and Fuc α (1 $\rightarrow$ O)Ser is indicated by the vertical lines that connect ROESY and TOCSY cross peaks. The numbers in the spectra refer to the protons in the respective glycosyl residues. (d) Schematic structure of the tetrasaccharide Neu5Ac α (2 $\rightarrow$ 6)Gal β (1 $\rightarrow$ 4)GlcNAc β (1 $\rightarrow$ 3)Fuc α (1 $\rightarrow$ O)Ser₆₁ of human Factor IX. The $\bullet$ — symbolizes an OH group. Sugar ring H atoms are not shown, with the exception of the GlcNAc H-1, Fuc H-3, Fuc H-1, and Ser H- β protons in order to illustrate their spatial arrangement relevant to the observed NOE effects

at 1.72 and 2.67 ppm, known to be sensitive to the linkage in which the residue is involved and the type of sugar to which it is attached, indicated that the Neu5Ac residue was $\alpha(2\rightarrow6)$ -linked to the Gal residue (compare Figure 3). Furthermore, the Gal H-1 chemical shift of 4.43 ppm and its coupling $^3J(\text{H-1,H-2})$ of 7.8 Hz were characteristic of its involvement in a $\beta(1\rightarrow4)$ linkage to GlcNAc in a sialyl-*N*-acetylactosamine moiety. Likewise, the positions and coupling constants for the Fuc [4.92 ppm; $^3J(\text{H-1,H-2}) = 4.2$ Hz] and GlcNAc H-1 [4.71 ppm; $^3J(\text{H-1,H-2}) = 8.0$ Hz] signals indicated the involvement of these residues in α - and β -glycosidic linkages, respectively. At this point, it was evident from the NMR data that the tetrasaccharide consisted of a terminal Neu5Ac $\alpha(2\rightarrow6)$ Gal $\beta(1\rightarrow4)$ GlcNAc $\beta(1\rightarrow\bullet)$ moiety and an α -linked Fuc residue.

To complete the structural analysis of the tetrasaccharide, 2D NOE experiments were performed in order to gather information about the distance between pairs of protons and, thus, sequence information. A ROESY spectrum of the glycopeptide provided a number of transglycosidic NOEs [Figure 6(c)]. Among them were a NOE between GlcNAc H-1 and the proton resonating at 4.06 ppm assigned to Fuc H-3 by TOCSY, and a NOE between Fuc H-1 and a proton at 3.72 ppm, i.e., one of the β -protons on Ser₆₁. The aforementioned interresidue NOE effects [between the protons highlighted in the schematic structure in Figure 6(d)] pointed to GlcNAc(1 $\rightarrow$ 3)Fuc and Fuc(1 $\rightarrow$ O)Ser linkages, respectively. Thus, NMR spectroscopy allowed the unambiguous establishment of the linearity of the tetrasaccharide's structure. Fuc was found present in this tetrasaccharide as an internal residue, providing the 'bridge' between GlcNAc in the sialyl-*N*-acetylactosamine moiety and Ser in the peptide. The NMR data are therefore compatible with the structure Neu5Ac $\alpha(2\rightarrow6)$ Gal $\beta(1\rightarrow4)$ GlcNAc $\beta(1\rightarrow3)$ Fuc $\alpha(1\rightarrow\text{O})$ Ser₆₁.

The methodology described here is generally applicable for the complete primary structure analysis of carbohydrates as free oligosaccharides and as constituents of glycoconjugates; anomeric configurations and positions of all glycosidic linkages and, indeed, full sequences can be unraveled. The only potential problem is that $^1\text{H}/^1\text{H}$ transglycosidic NOEs are not always the largest magnitude interresidue NOEs. The resulting ambiguity in the definition of the linkage position, however, can be solved by ^1H -detected $^{13}\text{C},^1\text{H}$ multiple-bond correlation (HMBC) spectroscopy.⁷¹ Detailed applications of this technique for glycoprotein oligosaccharides have been described.⁷² Briefly, when ^{13}C and ^1H NMR spectroscopy are used together, NMR demonstrates its real power in the de novo delineation of carbohydrate structures from first principles. Heteronuclear $^{13}\text{C},^1\text{H}$ correlation NMR techniques are the most informative NMR experiments for carbohydrate primary structures.^{72,73} The sensitivity limitations for these types of experiments were overcome by the introduction of the ^1H -detected versions of many $^{13}\text{C},^1\text{H}$ correlated spectroscopies. The HMQC experiment, providing a one-bond $^{13}\text{C},^1\text{H}$ correlation map, is generally sufficient to assign unambiguously all resonances in the ^{13}C NMR spectrum, provided that the entire ^1H spectrum is assigned by the COSY/TOCSY approach. The tracing of long-range transglycosidic $^3J(\text{C,H})$ values from the HMBC spectrum completes the primary structural analysis by unambiguously providing the linkage positions and the sequence of the glycosyl residues in the complex carbohydrate. Heteronuclear correlation experiments also allow

the location of appended noncarbohydrate groups (such as acetates⁷⁴ and phosphates⁷⁵) in oligosaccharides. For further examples, see the article by Bush (*Polysaccharides and Complex Oligosaccharides*) in this Encyclopedia.

At the present time, the NMR methodology for nondestructively deciphering any unknown carbohydrate primary structure is available. Isolating and purifying carbohydrates in amounts sufficient to perform these analyses is currently the bottleneck to their structural characterization.

4 THE PRESENT: SOLUTION CONFORMATION AND DYNAMICS

Due to the competition of more sensitive procedures, NMR spectroscopy may not always be the method of choice for the de novo determination of oligosaccharide primary structures. However, NMR spectroscopy easily outperforms any other available method of structural analysis when molecular conformation and motional characteristics are the focus of attention, and it yields the most complete picture of oligosaccharide structure and dynamic behavior in solution. A knowledge of conformation and dynamics is essential to understanding how oligosaccharides mediate biological recognition on cell surfaces. The NMR parameters holding the key information regarding oligosaccharide conformation and flexibility include scalar and dipolar couplings, relaxation times, and chemical exchange rates. Section 4.1 discusses how these parameters can be related to internuclear distance and torsion angle information and, therefore, to pyranose ring pucker, ensembles of rotamers around bonds that allow for certain flexibility, glycosidic linkage conformation, hydrogen bonding, and rotational correlation times for molecular tumbling and internal motions. Section 4.2 highlights some of the multipulse NMR spectroscopic techniques currently used to gather the constraints required to define the conformation and dynamics of an oligosaccharide in aqueous solution. Noteworthy review articles dealing with the application of multipulse *n*D NMR for carbohydrate conformational analysis are available.^{9,18,55,58,59,64,66,72,76–78} Most of the NMR methodology reviewed in this section will be concerned with selective excitation experiments^{79,80} which, for carbohydrates, are extremely useful in the retrieval of any desired information from NMR spectra. Upon critical evaluation of this information, it becomes clear that all oligosaccharides are, to a greater or lesser extent, flexible. The number of conformers adopted by small oligosaccharides is, however, not infinitely large; even oligosaccharides that include a (1 $\rightarrow$ 6) linkage fluctuate between a relatively small number of rather well-defined conformations. As an example, the process of deriving an ensemble of conformations from a sufficiently large set of NMR constraints is illustrated for sialyl- $\alpha(2\rightarrow\text{b})$ lactose. This discussion will be followed immediately by the description of NMR experiments which are capable of revealing internal motion in an oligosaccharide for which, at first glance, all measured NMR constraints seem to favor a rigid-body model. For example, we demonstrate that sucrose, the disaccharide that for years has been the paradigm of carbohydrate rigidity in solution, more than likely experiences fast internal motion around its glycosidic bond. Finally, Sections 4.3 and 4.4 will summarize the current knowledge on glycoprotein and glycolipid carbohydrate conformations and dynamics.

Figure 7 (a) Definition of the chair conformations of d-hexopyranose rings (a = axial substituent). For most monosaccharides, the 1C_4 and 4C_1 chairs are energetically favored over any boat conformers. For example, Man and Gal typically adopt the 4C_1 chair conformation, while Fuc and Neu5Ac adopt the 1C_4 chair (called the 2C_5 chair for Neu5Ac) [see Figure 1(c)]. (b) Definition of the torsion angles ϕ and ψ around a typical glycosidic linkage [in this case, the (1 $\rightarrow$ 4) linkage in lactose]: $\phi = \text{H}-1-\text{C}-1-\text{O}-1-\text{C}-4'$ and $\psi = \text{C}-1-\text{O}-1-\text{C}-4'-\text{H}-4'$. In conjunction with ${}^3J(\text{H}-1, \text{C}-4')$ and ${}^3J(\text{C}-1, \text{H}-4')$ the NOE between H-1 and H-4' across the glycosidic bond is used for linkage conformation analysis

4.1 Three-Dimensional Carbohydrate Structure

Once an oligosaccharide's primary sequence has been elucidated, its 3D structural characterization is typically approached in the following steps: (i) the ring conformation for each of the constituent glycosyl residues is defined [see Figure 7(a)]; (ii) the intraresidue conformation is completed by attempting to define, relative to the ring, the conformation(s) of any pendant (CH_2OH and OH) groups; (iii) the conformations of each of the glycosidic linkages in the oligosaccharide are characterized [see Figure 7(b)]; and (iv) additional distance constraints which could be indicative of hydrogen bonding or other types of interaction between residues, both adjacent and nonadjacent in the primary structure, are sought. Oligosaccharide conformations are ultimately defined in terms of the relative (Cartesian or spherical) coordinates of the atoms in 3D space; these coordinates are obtained via the measurement of internuclear distances and torsion angles around bonds. The pioneering work of Solomon⁸¹ and Karplus^{13,82} has demonstrated the possibility of probing the geometry of molecules in solution via NMR by measurements of NOE effects and scalar couplings, respectively. NOE effects are dependent on internuclear distance, while scalar couplings between nuclei separated by three chemical bonds (3J) depend on the dihedral angle between two planes containing those nuclei. The advent of multidimensional and multinuclear spectroscopy enabled the measurement of a large number of homo- and heteronuclear NOE contacts and vicinal coupling constants, including those from extremely overlapped oligosaccharide NMR spectra. If a sufficient number of constraints can be obtained from

NMR, the 3D structure(s) of the carbohydrate can be computed.^{66,76,83} Carbohydrate NMR has reached a level of sophistication at which the number of detectable constraints is sometimes large enough to be incompatible with a single rigid conformer, prompting the consideration of ensemble average models. Help is then sought from molecular modeling (potential energy calculations) to provide candidate low-energy structures that may contribute to the ensemble average. Sometimes, rather deceptively, all measured constraints seem to favor one rigid conformation for the oligosaccharide in question. In these cases, it is particularly important to remember to take into consideration that J and NOE values are intrinsically motionally averaged. Perhaps more often, modeling of carbohydrates is hampered by the existence of very few detectable NOE contacts. Unfortunately, the number of detectable structural constraints usually proves insufficient to unambiguously define the carbohydrate's conformation. The latter phenomenon is most often attributed to more pronounced conformational flexibility.⁵⁸ As soon as carbohydrate NMR spectroscopists became aware of the dynamic nature of oligosaccharides, they attempted to measure NMR parameters which could be used to characterize internal motions more quantitatively. Internal motion in biomolecules can be detected and quantified by NMR spectroscopy if it occurs relatively slowly or relatively quickly compared with the overall motion of the molecule.⁸⁴ NMR parameters that can be related to internal dynamics include the temperature and magnetic-field-strength dependences of relaxation times (T_1 and $T_{1\rho}$) and cross-relaxation rates (homo- and heteronuclear NOEs).⁸⁵

4.1.1 Conformation

For the determination of pyranoid ring conformations, a complete set of vicinal ${}^3J(\text{H}, \text{H})$ couplings for the spin system suffices due to the relative rigidity of this type of ring structure. One or more intraresidue ${}^1\text{H}/{}^1\text{H}$ NOEs may be useful in refining the pyranose ring pucker. Conformations of pendant groups require the measurement of all pertinent vicinal $J(\text{H}, \text{H})$ scalar couplings [for example, ${}^3J(\text{H}-5, \text{H}-6)$ and ${}^3J(\text{H}-5, \text{H}-6')$ for CH_2OH in hexopyranoses; ${}^3J(\text{HOCH})$ couplings for OH groups]. Additionally, ${}^1\text{H}/{}^1\text{H}$ NOEs and heteronuclear scalar couplings may be measured. For the conversion of ${}^3J(\text{H}, \text{H}')$ scalar couplings into torsion angles, carbohydrate spectroscopists use the Karplus equation as parameterized by Haasnoot et al. to account for substitution and electronegativity effects along the $\text{H}-\text{C}-\text{C}'-\text{H}'$ pathway^{86,87} [see also Altona (*Vicinal Coupling Constants and Conformation of Biomolecules*) in this Encyclopedia]:

$${}^3J(\text{H}, \text{H}') = 13.22 \cos^2 \theta - 0.99 \cos \theta + \sum_i \Delta \chi_i [0.87 - 2.46 \cos^2(\xi_i \theta)] \quad (1)$$

where θ is the $\text{H}-\text{C}-\text{C}'-\text{H}'$ torsion angle, and $\Delta \chi_i$ are the Huggins electronegativities of substituent i relative to that of H. The value of ξ_i is either +1 or -1, depending on the orientation of the substituents.⁸⁶ As for the pendant groups, the conformation of the hydroxymethyl group in hexopyranoses is predominantly determined by the rotation around the C-5-C-6 bond described by the dihedral angle ω_{H} (Figure 8). As was reviewed by Bock and Duus,⁸⁸ information about the

Figure 8 Definition of the three staggered conformations for the hydroxymethyl group in d-glucopyranose. For NMR spectroscopy, ω_H is defined as the dihedral angle H-5-C-5-C-6-O-6. (In crystallography, ω is commonly defined as O-5-C-5-C-6-O-6; hence, the subscript H in ω_H when using H-5 as the reference atom.) The three staggered conformers are described as *gg*, *gt*, and *tg* (*g* = *gauche*, *t* = *trans*; the first letter in the pair refers to the O-6 position relative to O-5, the second to the orientation of O-6 with respect to C-4). Thus, *gg*, *gt*, and *tg* correspond to $\omega_H = 180^\circ$, 60° , and -60° , respectively

conformational preferences of the hydroxymethyl group can be obtained via NMR using $^3J(\text{H-5, H-6R})$ and $^3J(\text{H-5, H-6S})$ provided that the stereospecific assignment of the H-6 atoms is either known or can be achieved via NMR.⁸⁹

$$^3J(\text{H-5, H-6R}) = 13.22 \cos^2 \theta - 0.99 \cos \theta - 6.4 \cos^2(25.87 - \theta) - 0.96 \cos^2(7.96 + \theta) + 2.61 \quad (2a)$$

$$^3J(\text{H-5, H-6S}) = 13.22 \cos^2 \theta - 0.99 \cos \theta - 3.2 \cos^2(25.87 - \theta) - 3.2 \cos^2(25.87 + \theta) - 0.96 \cos^2(7.96 + \theta) + 2.61 \quad (2b)$$

If one assumes that the three low-energy staggered rotamers ($\omega_H = 60^\circ$, -60° , and 180°) (Figure 8) are the exclusive contributors to the average conformer, the measured values $[^3J(\text{H-5, H-6R})]_{\text{exp}}$ and $[^3J(\text{H-5, H-6S})]_{\text{exp}}$ are analyzed as linear combinations of the calculated values of these couplings for the pure *gg*, *gt*, and *tg* rotamers; the coefficients p_{gg} , p_{gt} , and p_{tg} in these equations are interpreted as relative populations, i.e., the mole fractions in which the respective staggered rotamers contribute to the time-averaged conformation as measured by NMR:

$$J_{\text{exp}} = p_{gg} \cdot J_{gg} + p_{gt} \cdot J_{gt} + p_{tg} \cdot J_{tg} \quad (3a,b)$$

(where J_{exp} is $^3J(\text{H-5, H-6R})$ or $^3J(\text{H-5, H-6S})$)

$$p_{gg} + p_{gt} + p_{tg} = 1 \quad (3c)$$

However, if constraints other than the two $^3J(\text{H-5, H-6})$ homonuclear couplings are available, it is not necessary to make the aforementioned assumption. More advanced methods applied to the analysis of the rotamer population around the C-5-C-6 bond use the conformational entropy (S) associated with an ensemble; S can be calculated as:

$$S = -R \sum_i p_i \ln p_i \quad (4)$$

where the sum is over all the conformations, p_i is the probability of the i th conformation occurring in the ensemble,

and R is the gas constant. Given the number of measurable NMR constraints, computerized methods attempt to maximize the conformational entropy.^{90,91}

Linkage conformations cannot be defined by $^nJ(\text{H,H}')$ measurements; their analysis requires the measurement of interglycosidic NOEs and ROEs (both $^1\text{H}/^1\text{H}$ NOE and ROE, and $^{13}\text{C}/^1\text{H}$ NOE, if possible), in combination with transglycosidic $^3J(\text{C,H})$ couplings. Distances are typically calculated as $r_{ij} = (igma_{\text{ref}}/\sigma_{ij})^{1/6} r_{\text{ref}}$, where σ_{ref} and r_{ref} are the cross-relaxation rate and the distance, respectively, of a pair of reference protons within the rigid pyranose ring system. Glycosidic bond angles are calculated from $^3J(\text{C,H})$ values according to the Karplus equation as parameterized by Tvaroska et al.⁹² (see also Mulloy et al.⁹³) based on seminal work by Perlin and co-workers.⁹⁴

$$^3J(\text{C, H}) = 5.7 \cos^2 \theta - 0.6 \cos \theta + 0.5 \quad (5)$$

where θ is the H-C-O-C torsion angle. In addition, $^1J(\text{C,H})$ values may be used to assist in the determination of bond conformations.^{95,96} If carbohydrates can be obtained uniformly or selectively ^{13}C isotopically-enriched,⁹⁷ long-range $^{13}\text{C}, ^1\text{H}$ couplings become easier to measure. In addition, $^1J(\text{C,C})$, $^2J(\text{C,C})$, and $^3J(\text{C,C})$ become detectable as conformational constraints. However, notwithstanding the advances that are being made in combining chemical and enzymatic syntheses, procedures to obtain uniformly ^{13}C isotopically-enriched ('labeled') carbohydrates, particularly glycoconjugate side chains, are by no means straightforward.

4.1.2 Hydrogen Bonding

Hydroxyl resonances in the ^1H NMR spectra of oligosaccharides in aprotic solvents such as DMSO have long been used as structural probes. However, as most biologists are primarily interested in carbohydrate conformations in aqueous solutions, only glycolipid NMR researchers have put any significant effort into investigating these signals in DMSO (Section 3.3). Although hydroxyl proton resonances in aqueous solutions of sugars were first observed over 14 years ago,⁹⁸ the utility of these protons in the conformational analysis of carbohydrates has been demonstrated only recently.^{99–103} Hydroxyl resonances potentially provide a wealth of structural information in the form of chemical shifts, J couplings, NOEs, exchange rates, and isotope shifts. However, this information is accessible only if the intermolecular exchange of OH protons with H_2O in the aqueous solvent can be slowed sufficiently. At room temperature, hydroxyl protons in aqueous solutions of carbohydrates engage in fast chemical exchange with water. Several researchers have applied mixed solvents (water/acetone and water/methanol) to study OH groups at low temperatures (-5°C to -10°C) (see, e.g., Poppe and Van Halbeek).⁹⁹ Recently, ^1H NMR studies of hydroxyl groups in dilute solutions of mono- and disaccharides in pure H_2O under supercooled (-15°C to -20°C) conditions have been reported.¹⁰¹ The chemical exchange effects under these conditions are reduced to such an extent that separate signals can be observed for each hydroxyl site; thus, all hydroxyl proton resonances can be assigned on the basis of scalar connectivities to nonlabile aliphatic protons. The scalar $^3J(\text{HOCH})$ couplings can be analyzed¹⁰³ by equations (1) and (3)^{3,43}, in conjunction with more advanced statistical methods. The linewidths,

temperature-shift coefficients, and coupling constants of OH protons are valuable hydration and hydrogen-bonding probes in NMR studies. H/D isotope effects of hydroxyl protons on ^{13}C resonances may be used to obtain additional evidence of the involvement of OH groups in intra- or interresidue hydrogen bonds.¹⁰⁴ Protruding farther from the glycosyl ring systems, OH protons may additionally serve as long-range sensor conformational probes which can be interrogated by NOESY and ROESY experiments of the carbohydrate in aqueous solution.^{99,105,106}

4.1.3 Dynamics

NOEs and ROEs (or, more strictly speaking, the cross-relaxation rates $\sigma^{\parallel}$ and $\sigma^{\perp}$), as well as scalar coupling constants, are time-averaged parameters when the interconversion of conformers is fast on the NMR timescale.¹⁰⁷ However, interpretation of the measured NMR constraints in terms of the existence of several conformers and their interconversion rates is not easily accomplished. An extensive use of molecular modeling is usually required.^{66,76,83,107,108} The experimental approach to the problem of flexibility involves the measurement of different relaxation rates (^{13}C and ^1H T_1 and $T_{1\rho}$, as well as $^1\text{H}/^1\text{H}$ and $^{13}\text{C}/^1\text{H}$ NOE) at a number of different frequencies (ω) in order to sample the spectral density $J(n\omega)$.^{109–112}

$$J(n\omega) = \left(\frac{2}{5}\right) \cdot \frac{\tau_c}{1 + (n\omega\tau_c)^2} \quad (6)$$

where $n = 0, 1$, or 2 , and τ_c , the rotational correlation time, is directly related to relaxation times T_1 and $T_{1\rho}$ (see, for example, Wagner and others).^{112–115} The laboratory and rotating frame homonuclear cross-relaxation rates, $\sigma^{\parallel}$ and $\sigma^{\perp}$, respectively, are expressed by equations (7a) and (7b):

$$\sigma^{\parallel} = K[6J(2\omega) - J(0)] \quad (7a)$$

$$\sigma^{\perp} = K[3J(\omega) + 2J(0)] \quad (7b)$$

where $K = 0.1 \Sigma_l \gamma^4 h^2 / 4\pi^2 r_{kl}^6$, γ is the ^1H gyromagnetic ratio, h is Planck's constant, r is the internuclear distance between nuclei k and l , and the summation index runs over all interactions.^{113,114,116} Similar expressions for $^{13}\text{C}/^1\text{H}$ cross-relaxation rates have been documented.¹¹²

Spectral density is most conveniently interpreted at the molecular level by the model-free approach of Lipari and Szabo^{117,118} in which the types of molecular motion of an oligosaccharide are distinguished by their different timescales. The total motion of the molecule is separated into the tumbling of the entire molecule (with rotation correlation time τ_o) modulated by more rapid internal (segmental) motion with characteristic correlation time (τ_i) and amplitude expressed by an order parameter (S^2):

$$J(n\omega) = S^2 \left(\frac{2}{5}\right) \cdot \frac{\tau_o}{1 + (n\omega\tau_o)^2} + (\langle r^{-6} \rangle - S^2) \left(\frac{2}{5}\right) \cdot \frac{\tau}{1 + (n\omega\tau)^2} \quad (8a)$$

where $n = 0, 1$, or 2 , $S^2 = \sum_{m=-2}^{m=2} |\langle (5/4\pi)^{-1/2} Y_{2m}(\Omega) / r^3 \rangle|^2$, $Y_{2m}(\Omega)$ are spherical harmonics functions with r and Ω

corresponding to the distance and polar angle of a given proton pair in the molecular frame; $\langle \dots \rangle$ denotes ensemble average; and $\tau^{-1} = \tau_o^{-1} + \tau_i^{-1}$. A slightly more simplified expression for $J(n\omega)$ may be used when taking only fluctuations due to molecular reorientation, but not internuclear separation, into account (Section 5.2); S^2 becomes distance independent, and equation (8a) becomes equation (8b):

$$J(n\omega) = S^2 \left(\frac{2}{5}\right) \cdot \frac{\tau_o}{1 + (n\omega\tau_o)^2} + (1 - S^2) \left(\frac{2}{5}\right) \cdot \frac{\tau}{1 + (n\omega\tau)^2} \quad (8b)$$

Either way, the generalized order parameter is a measure of the spatial restriction of the internal reorientation ($S^2 = 1$ in the absence of internal motion; $S^2 = 0$ in the presence of complete, isotropic reorientation).

Often applicable to oligosaccharides, this model predicts that, if there is significant relaxation through internal motion in the saccharide, the ratio of the NOEs (and the T_1 values) at different field strengths should differ for those protons relaxing with neighboring protons within fixed distances (i.e., neighbors on the same pyranose ring) versus those relaxing with neighbors at fluctuating distances (i.e., across the glycosidic linkage). The separation of the motions into distinct regimes is crucial to the success of this method. For internal motions to contribute significantly to the relaxation, their time scale must be fast compared with that of the overall tumbling (i.e., $\tau_o \sim 0.1$ ns for a disaccharide). Thus the internal dynamics (segmental motions) of carbohydrate molecules in solution can be assessed by NMR spectroscopy if the rearrangements occur much faster (or much slower) than the overall molecular tumbling. Physical models for the temperature dependences of τ_o , τ_i , and NOEs are in existence as well, but they are less successful in reproducing the dynamic behavior of oligosaccharides.

4.2 Di- and Trisaccharides

Analyses of the solution conformation and dynamics of carbohydrates encompass the following steps: (i) the complete assignment of ^1H and ^{13}C NMR spectra of the carbohydrate, (ii) the measurement of NOEs and vicinal couplings in order to establish spatial (distance and/or torsion angle) constraints between atoms, (iii) the measurement of ^1H and ^{13}C relaxation parameters (T_1 , $T_{1\rho}$, homo- and heteronuclear NOEs) as a function of temperature and field strength, and (iv) the evaluation of experimental data with the use of computational strategies, including statistical methods, potential energy calculations, and molecular dynamics (MD) or Monte Carlo (MC) simulations (as well as comparison with crystal structures, if available). With the application of at least two of the aforementioned steps, a large number of di- and trisaccharides have been examined, including sucrose (see below), maltose [$\text{Glc}\alpha(1\rightarrow4)\text{Glc}$],¹¹⁹ cellobiose [$\text{Glc}\beta(1\rightarrow4)\text{Glc}$],¹²⁰ lactose [$\text{Gal}\beta(1\rightarrow4)\text{Glc}$],^{97,121} melibiose [$\text{Gal}\alpha(1\rightarrow6)\text{Glc}$],¹²² gentiobiose [$\text{Glc}\beta(1\rightarrow6)\text{Glc}$] (see below), xylobiose [$\text{Xyl}\beta(1\rightarrow4)\text{Xyl}$],¹²³ mannobioses [$\text{Man}\alpha(1\rightarrow3)\text{Man}$ and $\text{Man}\alpha(1\rightarrow2)\text{Man}$],^{108,124} chitobiose [$\text{GlcNAc}\beta(1\rightarrow4)\text{GlcNAc}$], and chitotriose. For an overview of

Figure 9 Schematic structure of sialyl- $\alpha(2\rightarrow6)$ -lactose. The numbering of the carbon atoms and their substituents is indicated. The torsion angles ϕ and ψ around the (1 $\rightarrow$ 4) glycosidic bond are defined as in Figure 7(b): $\phi(\text{H-1}'\text{-C-1}'\text{-O-1}'\text{-C-4})$ and $\psi(\text{C-1}'\text{-O-1}'\text{-C-4-H-4})$. The angles ϕ and ψ around the (2 $\rightarrow$ 6) glycosidic linkage are defined as $\phi(\text{C-1}'\text{-C-2}'\text{-O-2}'\text{-C-6})$ and $\psi(\text{C-2}'\text{-O-2}'\text{-C-6-C-5})$, while ω is (O-5-C-5-C-6-O-2'); the definition of ϕ differs from that given in the legend to Figure 7(b) due to the absence of an anomeric proton in Neu5Ac. The conformation of the (1 $\rightarrow$ 4) linkage was studied by measuring $^3J(\text{H-1}',\text{C-4})$ and $^3J(\text{C-1}',\text{H-4})$ (compare Figure 14), as well as interglycosidic NOEs. Angle ϕ for the (2 $\rightarrow$ 6) linkage was studied by $^1\text{H}/^1\text{H}$ ROE and $^{13}\text{C}/^1\text{H}$ NOE experiments, while ψ for the (2 $\rightarrow$ 6) linkage was deduced from $^3J(\text{C-2}',\text{H-6R})$ and $^3J(\text{C-2}',\text{H-6S})$ measurements (Table 2). For ω around the (2 $\rightarrow$ 6) linkage, the Gal $^3J(\text{H-5},\text{H-6R})$ and $^3J(\text{H-5},\text{H-6S})$ were measured (Figure 13 and Table 1).¹⁰⁶ The Neu5Ac glycerol side-chain conformation was defined by the $^3J(\text{H-6},\text{H-7})$, $^3J(\text{H-7},\text{H-8})$, $^3J(\text{H-8},\text{H-9})$ and $^3J(\text{H-8},\text{H-9}')$ couplings (for the latter two, see Figure 12) in conjunction with the existence of a hydrogen bond between O-8 and the C-O bond of the C-1 carboxyl group.¹⁰⁶

di- and trisaccharide structures determined by X-ray crystallography, NMR spectroscopy and/or theoretical computations, the reader is referred elsewhere.^{77,125–128} Because of the importance of sialyl oligosaccharides in the biology of glycoproteins and glycolipids, an illustration is provided of the typical procedures involved in the NMR conformational analysis of a trisaccharide similar to the terminal entity found on various glycoprotein and ganglioside oligosaccharides, namely, sialyl- $\alpha(2\rightarrow6)$ -lactose [Neu5Ac $\alpha(2\rightarrow6)$ Gal $\beta(1\rightarrow4)$ Glc].¹⁰⁶ Comparisons are drawn with the conformations of Neu5Ac $\alpha(2\rightarrow3)$ Gal¹²⁹ and sialyl- $\alpha(2\rightarrow3)$ -lactose.¹³⁰ A schematic drawing of the structure of sialyl- $\alpha(2\rightarrow6)$ -lactose is shown in Figure 9, and definitions of torsion angles ϕ , ψ , ω , and other pertinent parameters are included in the legend to that figure.

4.2.1 ^1H and ^{13}C Spectral Assignments

Attractive alternatives to the 2D COSY and TOCSY techniques currently used for the complete assignment of the ^1H NMR spectrum of an oligosaccharide (Section 3.4) are their 1D selective analogs.^{79,131} Despite the overlap of $\sim 85\%$ of the aliphatic proton resonances within approximately 1 ppm in a typical carbohydrate spectrum, the resonances of the structural-reporter groups, including those of the anomeric protons, are separated and accessible for selective excitation, providing suitable entries for transfer of magnetization through scalar couplings to other protons in the spin system of a glycosyl residue. In fact, carbohydrates are often cited in the magnetic resonance literature as being used as toy systems for new selective excitation sequences (see Kupce and Freeman,¹³² for example). To reveal the entire spin system, i.e., trace the scalar connectivity from H-1 through H-6 for a hexosyl residue, two methods are currently being applied; (i) multistep correlated (relayed COSY) experiments^{133,134} in which magnetization is transferred in successive steps from

the selectively excited resonance, and (ii) isotropic mixing (TOCSY) pulse sequences^{62,135} that distribute selectively excited magnetization in a more uniform manner among coupled spins. Magnetization transfer in TOCSY experiments is more efficient than in relayed COSY experiments, which suffer from larger losses of magnetization due to T_2 relaxation; also, TOCSY signals occur as in-phase multiplets. The major obstacles to tracing glycosyl spin systems are small coupling constants (e.g., those between H-1 and H-2 in mannosyl, H-4 and H-5 in galactosyl, and H-6 and H-7 in Neu5Ac residues). In order to overcome these ‘bottlenecks’ in TOCSY experiments, researchers have applied a number of different schemes which rely on multiple selective excitation, e.g. double-TOCSY¹³⁶ or double-DANTE TOCSY¹³⁷ or relayed TOCSY¹³⁸ (where isotropic mixing is followed by a COSY step). Parenthetically, it should be mentioned that extensions of ^1H 1D and 2D techniques to 3D and 4D NMR techniques have been described for carbohydrates;^{139,140} however, full-blown 3D and 4D data acquisition is time-consuming and rarely necessary to solve a carbohydrate structural problem. (Multi-)selective 1D and 2D analogs of 3D and 4D NMR experiments^{80,141} are far more efficient methods of obtaining the desired information from a carbohydrate ^1H NMR spectrum. For example, the 2D selective analog of the 3D TOCSY-COSY experiment and the 3D selective analog of the 4D TOCSY-TOCSY-COSY experiment have been applied for tracing scalar connectivities in GlcNAc residues for medium-sized oligosaccharides.^{140,142} Pulse sequences which are successfully utilized for isotropic mixing include: MLEV-17,⁶² WALTZ-16,¹⁴³ DIPSI-2,¹⁴⁴ clean-CITY,¹⁴⁵ and mixing sequences proposed by Glaser and Drobny.¹⁴⁶ Selective excitation is accomplished by DANTE pulse trains¹⁴⁷ or any one of a variety of shaped pulses.^{79,80,148}

Once the ^1H NMR spectrum of an oligosaccharide has been assigned, the assignment of the protonated ^{13}C resonances on the basis of one-bond $^{13}\text{C},^1\text{H}$ correlation spectroscopy (e.g., HMQC) is relatively straightforward (Section 3.4). Nonprotonated ^{13}C signals can be assigned by an HMBC experiment. These ^1H -detected (or ‘inverse-detected’) schemes¹⁴⁹ allow the acquisition of correlation spectra for submillimolar amounts of carbohydrate sample within a few hours of data acquisition. Employing the combination of TOCSY and HMQC/HMBC spectroscopy, the ^1H and ^{13}C spectra of sialyl- $\alpha(2\rightarrow6)$ -lactose in D_2O have been fully assigned.¹⁰⁶

4.2.2 Distance and Torsion Angle Constraints

4.2.2.1 Ring Conformation. The establishment of pyranose ring pucker involves the accurate measurement of homonuclear vicinal scalar couplings; this is best accomplished with the use of ^1H selective excitation experiments such as 1D TOCSY [Figure 10(a)]. The signals in 1D TOCSY spectra are obtained in pure absorption if the admixture of antiphase dispersive lines is averaged out by stepwise incrementation of the isotropic mixing time¹³⁵ or by incorporation of a z filter.⁶² The values of the $^3J(\text{H},\text{H}')$ couplings acquired for sialyl- $\alpha(2\rightarrow6)$ -lactose¹⁰⁶ show each of the ring systems in the trisaccharide to be in its typical pyranose chair conformation, i.e., $^4\text{C}_1$ for Glc and Gal, $^2\text{C}_5$ for Neu5Ac [compare Figures 1(c) and 7, and Sabesan et al.].¹⁵⁸

4.2.2.2 Exocyclic Groups. In order to evaluate rotamer populations around the C-5–C-6 bond in hexopyranoses, the

Figure 10 Pulse sequences commonly used for ^1H selective excitation experiments on carbohydrates. Selective excitation uses either a composite 90° pulse¹⁵⁰ consisting of two consecutive DANTE pulse trains,¹⁴⁷ traces (a)–(d) or a DANTE- z sequence¹⁵¹ consisting of two interleaved pulse trains with different phase properties, trace (e). In all cases, $\Delta \sim 0.63t_{90}$, where t_{90} is the duration of the selective 90° pulse. The basic phase cyclings, as listed, may be extended following CYCLOPS and EXORCYCLE procedures.¹⁵² (a) 1D TOCSY or 1D ROESY experiment. Isotropic mixing is performed with¹⁴⁶ composite pulses $R = (290^\circ_x, 330^\circ_{-x}, 290^\circ_x)$ arranged into the supercycle (*RRRR RRRR RRRR RRRR*, 180°_y) analogous to the MLEV-17 sequence;¹⁵³ italicized letters indicate phase inversion of the element. The mixing time is flanked by two short (~ 2 ms) trim pulses. For mixing in the ROESY experiment, a train of short ($\sim 20^\circ$) pulses is used.¹⁵⁴ (b) 1D NOESY experiment. (c) Selective 3D TOCSY–ROESY experiment.^{150,155} (d) Double selective 3D TOCSY–ROESY experiment. The selective α pulse, when achieved with a DANTE pulse train,¹⁵⁶ can have any tilt angle in the range of 60° to 180° . The phase increment $\delta\phi$, associated with the change of offset during a finite time interval, is determined experimentally. (e) 1D experiments in H_2O solution utilizing 1–1 echo water suppression.¹⁵⁷ The DANTE- z pulse train can be used either for spin inversion or presaturation. The delay Δ determines the width of the excitation profile; typical values of Δ tailored for carbohydrate NMR spectra are 200–400 μs . A short (~ 2 ms) spin lock pulse may serve to purge the dispersive part of the residual water signal. The experiments are typically performed in the difference mode, with pertinent shift of carrier frequencies, using a single power level of excitation (typically $t_{90} \sim 60 \mu\text{s}$)

protons in the exocyclic CH_2OH group must be assigned stereospecifically. Since the methylene protons, together with ring proton H-5, form a mutually coupled three-spin system, they can be recognized with, for example, a 2D triple quantum filtered COSY⁷⁶ or triple quantum correlated spectroscopy experiment.^{64,78,159,160} Proton multiplets from

exocyclic groups are more readily retrievable from selective 1D TOCSY spectra or, alternatively, from 1D COSY spectra recorded with a chemical-shift-selective filter.^{161,162} If the pertinent coupling constants cannot be accurately measured from such ^1H spectra, either due to extreme spectral overlap or second-order effects, then the goal can be attained with inverse ^{13}C , ^1H correlation experiments in which the proton multiplets are more likely to occur separately due to the larger chemical shift dispersion in the ^{13}C spectrum. Usually, the method of choice is the modified over-Bodenhausen experiment¹⁶³ as depicted in Figure 11(a); this selective 1D heteronuclear single quantum coherence (HSQC) experiment gives pure absorptive ^1H lineshapes. An additional advantage of this pulse sequence lies in the ease with which it can be applied selectively; this is accomplished by either replacing the first ^{13}C 180° pulse with its selective analog¹⁶⁹ or by performing t_1 incrementation in analogy to a chemical-shift-selective filter (by jittering of delay, δ).^{161,166} Application of this method to sialyl- $\alpha(2\rightarrow6)$ -lactose yields well separated, first-order H-9R and H-9S multiplets for the Neu5Ac side chain (Figure 12).

The stereospecific assignment of the exocyclic methylene protons is particularly critical when analyzing the conformation of a (1 $\rightarrow$ 6) linkage between two glycosyl residues [for example, the linkage between Neu5Ac and Gal in sialyl- $\alpha(2\rightarrow6)$ -lactose (Figure 9)]. When the stereospecifically mono-C-6 (or mono-C-9, if Neu5Ac is concerned) deuterated analogs of the oligosaccharide are available, the assignment of H-6R (H-9R) and H-6S (H-9S) is readily accomplished. However, the stereospecific chemical synthesis of a mono-C-6-deuterated analog of a mono- or disaccharide is usually a rather laborious procedure. Fortunately, NMR spectroscopy can, for some oligosaccharides, assign the C-6 methylene protons stereospecifically without the aid of deuteration. To accomplish this, one needs to be able to measure the pertinent vicinal $^3J(\text{H-5}, \text{H-6})$ and $^3J(\text{H-5}, \text{H-6}')$ coupling constants in conjunction with either the H-4/H-6,6' NOE effects⁷⁸ or the $^3J(\text{C-4}, \text{H-6})$ and $^3J(\text{C-4}, \text{H-6}')$ scalar couplings.^{89,170} The measurement of heteronuclear coupling constants will be discussed later in this section. As to the stereospecific assignment of H-6R and H-6S based on ‘NOE-labeling’, valuable spectral information can be obtained from selective analogs of 3D NOE-labeling experiments in many cases.^{80,150,171} Figure 13 shows a selective 3D TOCSY–ROESY spectrum obtained for sialyl- $\alpha(2\rightarrow6)$ -lactose with the pulse sequence shown in Figure 10(d). The NOE connectivities originating from Gal H-4 appear well-resolved. The values of the Gal $^3J(\text{H-5}, \text{H-6})$ coupling constants (Table 1), along with the observation of NOE between Gal H-4 and only one of the H-6 protons (Figure 13), enabled the stereospecific assignment of Gal H-6R and Gal H-6S.¹⁰⁶ Subsequent analysis of the vicinal $^3J(\text{H-5}, \text{H-6R})$ and $^3J(\text{H-5}, \text{H-6S})$ coupling constants using equations (3a)–(3c) provided the rotamer populations around ω for sialyl- $\alpha(2\rightarrow6)$ -lactose (Table 1). This interpretation was refined by the application of the maximum entropy method.⁹⁰ The availability of a relatively large set of structural constraints is required for this approach [for example, the values of the Gal $^3J(\text{H-5}, \text{H-6R}')$, $^3J(\text{H-5}, \text{H-6S}')$, $^3J(\text{C-4}, \text{H-6R})$ and $^3J(\text{C-4}, \text{H-6S})$ scalar couplings and the H-5/H-6R, H-5/H-6S, H-4/H-6R, and H-4/H-6S NOEs were used in the analysis of the rotameric distribution; see Table 2]. When applied to gentiobiose [Glc $\beta(1\rightarrow6)$ Glc] to characterize the conformational flexibility around the C-5–C-6 bond which is part of the disaccharide’s glycosidic linkage,

Figure 11 Pulse sequences for measuring long-range $nJ(\text{C,H})$ ($n = 2, 3, 4, \dots$) with ^1H detection. SL denotes spin lock; the other symbols are as defined in Figure 10. (a) Modified HSQC experiment.^{163–165} The pulse marked with x is either selective or nonselective. The delay δ is either systematically or stochastically incremented¹⁶⁶ to obtain selectivity in the carbon domain. The delay τ is taken long enough for the evolution due to heteronuclear long-range couplings to become manifest. The resulting proton multiplets are in antiphase with respect to one- or multibond $^{13}\text{C}, ^1\text{H}$ couplings and in-phase with respect to homonuclear couplings. (b) Modified HSQC and (c) relay TOCSY-HSQC experiments¹⁶⁷ tailored for measuring interglycosidic $^3J(\text{C,H})$ in oligosaccharides. (d) ^{13}C -selective 2D analog of a 3D exclusive-type $^{13}\text{C}, ^1\text{H}$ correlation experiment.¹⁶⁸ The ^{13}C 90° pulses are 1–2 ms long; $\tau \sim [2^1J(\text{C,H})]^{-1}$

Figure 12 Editing ^1H multiplets according to their ^{13}C chemical shift. Spectrum of sialyl- $\alpha(2\rightarrow6)$ -lactose in D_2O solution obtained with the pulse sequence shown in Figure 11(a); τ is set to 3 ms. The Neu5Ac C-9 frequency was selected by randomly jittering the delay δ . In the ^1H spectrum of the ^{12}C -9 isotopomer, H-8–H-9S–H-9R constitute a second-order ABX spin system; no value for the homonuclear coupling $^3J(\text{H-8}, \text{H-9S})$ can be derived from that spectrum (reproduced with permission from Escom Science Publishers)¹⁰⁶

the maximum entropy method yields results that differ significantly from the results of traditional rotameric distribution calculations employing force-field-based analysis of the $^3J(\text{H-5}, \text{H-6})$ couplings by a Karplus-type equation;⁹⁰ however, for sialyl- $\alpha(2\rightarrow6)$ -lactose that difference was insignificant.

4.2.2.3 Linkage Conformations from $^3J(\text{C}, \text{H})$. Long-range heteronuclear scalar couplings [$^3J(\text{C}, \text{H})$] through the glycosidic bonds ($\text{H}-\text{C}-\text{O}-\text{C}'$ and $\text{C}-\text{O}-\text{C}'-\text{H}'$) [Figure 7(b)] provide spatial constraints for the torsion angles ϕ and ψ , respectively, around the glycosidic linkages. Most of the NMR pulse sequences developed for the sensitive and accurate measurement of $^3J(\text{C}, \text{H})$ values for carbohydrates are based on the ^1H -detected HSQC experiment.^{163,164} The experiments can be conducted in true 2D or selective 2D mode by selective excitation and/or chemical-shift filtering of the protons and/or carbons of interest^{167,169,172} (Figure 11). If the proton of interest is not accessible for selective excitation, the anomeric proton of the relevant monosaccharide is excited first, and the magnetization is transferred to the desired proton by a TOCSY step preceding the HSQC experiment [Figures 11(c) and 14].¹⁶⁷ With the aid of these methods, the pertinent $^3J(\text{Glc C-4}, \text{Gal H-1})$ and $^3J(\text{Glc H-4}, \text{Gal C-1})$ couplings in sialyl- $\alpha(2\rightarrow6)$ -lactose were determined to be 4.2 and 5.1 Hz, respectively (Table 2).

As a valuable alternative to HSQC, a double INEPT type polarization transfer step may be used in the ^1H -detected measurement of long-range $^{13}\text{C}, ^1\text{H}$ couplings; examples of such ^1H - and ^{13}C -selective, ^1H -detected 2D and pseudo 2D experiments have been reported.¹⁷³ Selective and nonselective measurements of interglycosidic $^3J(\text{C}, \text{H})$ are greatly facilitated by the incorporation of ^{13}C labels at the positions involved in glycosidic linkages, as was demonstrated for sucrose.¹⁷⁴

The elusive long-range heteronuclear scalar coupling parameters are also present in 2D ^{13}C -filtered $^1\text{H}, ^1\text{H}$ correlation spectra, e.g., TOCSY¹⁷⁵ and NOESY/ROESY spectra,¹⁷⁶ which

Figure 13 Selective 3D TOCSY–ROESY spectrum of sialyl- $\alpha(2\rightarrow6)$ -lactose in D_2O solution (~ 30 mM) obtained with the pulse sequence shown in Figure 10(c) at 500 MHz and ambient temperature. The Gal H-1 proton was selectively excited (for 60 ms), followed by 77 ms of TOCSY and 140 ms of ROESY mixing. The digital resolution in the resulting 2D spectrum is 0.73 Hz pt^{-1} and 4.3 Hz pt^{-1} in the ω_2 and ω_1 dimensions, respectively; the total acquisition time was less than 5 h (reproduced with permission from Escom Science Publishers)¹⁰⁶

Table 1 Rotamer Distribution around Gal C-5–C-6 in Sialyl- $\alpha(2\rightarrow6)$ -Lactose

Coupling constant	4 °C	21 °C	77 °C
$^3J(\text{H-5}, \text{H-6R})$	8.5 ± 0.2	8.3 ± 0.2	7.8 ± 0.2
$^3J(\text{H-5}, \text{H-6S})$	3.7 ± 0.2	3.8 ± 0.2	4.2 ± 0.2
Population ^a	4 °C	21 °C	77 °C
p_{gg}	0.18 ± 0.03	0.20 ± 0.03	0.22 ± 0.02
p_{gt}	0.74 ± 0.03	0.71 ± 0.03	0.64 ± 0.02
p_{tg}	0.08 ± 0.03	0.08 ± 0.03	0.14 ± 0.02

^aCalculated from the vicinal coupling constants $^3J(\text{H-5}, \text{H-6R})$ and $^3J(\text{H-5}, \text{H-6S})$ using equations (3a)–(3c). See Figure 8 for explanation of g , g , g , t , t , t notation.

exhibit an exclusive type cross-peak structure. In these spectra, the long-range coupling constants are measured in the ω_2 dimension as a displacement of the proton multiplets that are resolved in the ω_1 dimension by the (large) $^1J(\text{C}, \text{H})$ coupling. One-dimensional versions of this experiment have been applied to carbohydrates^{89,177} to measure, for example, the $^3J(\text{C-4}, \text{H-6R})$ and $^3J(\text{C-4}, \text{H-6S})$ scalar couplings in glucose and galactose residues. Alternatively, a ^{13}C -filtered ROESY experiment has been introduced to measure $^3J(\text{C}, \text{H})$ coupling constants through the glycosidic bonds of a cyclic glucan.¹⁷⁸

Figure 14 The measurement of heteronuclear long-range coupling constants across a glycosidic linkage illustrated for lactose in D_2O (50 mg mL^{-1}). (a) Reference spectrum. (b) Spectrum obtained with the pulse sequence shown in Figure 11(b). A 1H composite pulse of 60 ms was applied selectively at Gal H-1, while the Glc ^{13}C -4 selective pulse was 2 ms long. (c) The heteronuclear coupling $^3J(C-4, H-1')$ causes the antiphase pattern of the observed Gal H-1 multiplet. It is evident from the 1D TOCSY traces (d), (e), and (f) that $^3J(C-1', H-4)$ cannot be obtained via the experiment shown in Figure 11(b) (note the overlap of Glc H-4 with Gal H-3); therefore, a relay TOCSY-HSQC experiment [Figure 11(c)] in which magnetization was selectively transferred from Glc α H-1 to H-4 was necessary (trace g). The duration of the entire pulse sequence in Figure 11(c) was close to 200 ms; 5500 scans were accumulated. (h) The heteronuclear coupling $^3J(C-1', H-4)$ is read from the antiphase structure of the observed Glc α H-4 multiplet, computer-simulated in trace (i). The values $^3J(C-4, H-1')$ and $^3J(C-1', H-4)$ are 4.0 and 5.1 Hz, respectively (reproduced with permission from Academic Press)¹⁶⁷

These methods, successfully applied to oligosaccharides with a natural abundance of ^{13}C , show their greatest potential in the measurement of long-range heteronuclear scalar couplings in ^{13}C isotopically-enriched carbohydrates (cf. Montelione et al.).¹⁷⁹ The pulse sequence in Figure 11(d) presents the selective version of 3D experiments originally designed for measurements of heteronuclear couplings in isotopically-enriched proteins.^{179,180} The long-range carbon–proton coupling constants are measured independently of the linewidth from the exclusive-type scalar couplings correlation patterns,^{168,179,180} as demonstrated (Figure 15) for glucose, 99% ^{13}C -labeled at

Table 2 Average Distances and Vicinal Coupling Constants for Sialyl- $\alpha(2\rightarrow6)$ -Lactose in Aqueous Solution¹⁰⁶

^aThe distances r_{app} were evaluated with the formula $r_{ij} = r_{kl}(I_{kl}/I_{ij})^{1/6}$, in which I_{ij} and I_{kl} are the integrated signal intensities; I_{kl} corresponds to a reference interaction. For ROESY spectra, the intensities were scaled by the offset dependent factors $(\sin \theta_i \cdot \sin \theta_j)^{-2}$, in which $\theta_i = \arctan(\omega_i/(\gamma B_1))$; ω_i represents the offset from the carrier frequency and $\langle \gamma B_1 \rangle$ the effective field strength in Hz. The precision of the distances is estimated to be $\sim 0.1r$.

^bThe precisions of the J_{exp} values are ± 0.2 Hz, except those of $^3J(C-1, H-4)$ (± 0.4 Hz) and $^3J(C-4, H-6R)$ and $^3J(C-4, H-6S)$ (± 0.2 Hz).

^cMMC simulated distances¹⁰⁶ were calculated according to the formula $\langle r^{-3} \rangle^{-1/3}$. The $\langle r_{sim} \rangle$ and J_{sim} values were scaled to 27 °C.

^dFamily I corresponds to the MMC simulation that started with ϕ of the (2→6)-linkage being set to -60° ; for family II, the pertinent angle was set to 180° .

^eThis distance reflects the occurrence of a hydrogen bond between Neu5Ac OH-7 and Glc O-3.

^fSee Table 1.

^gCompare with Figure 14.

^hAn anomerization effect ($\Delta\delta_{\alpha-\beta}$) was observed for Gal H-6R, but not for Gal H-6S, indicating that the former proton is closer to the Glc reducing end, i.e. near O-3 of the Glc residue; see Figure 16.

C-1. Furthermore, the direction of the multiplet displacements allows the determination of the signs of the relevant coupling constants (cf. Serianni and Podlasek).¹⁸¹

4.2.2.4 Linkage Conformations from Interresidue $^1H/^1H$ NOE. Early in the history of carbohydrate NMR, conformational studies of small and medium-sized oligosaccharides in solution were based on steady-state NOE measurements.¹¹³

Figure 15 The measurement of heteronuclear coupling constants $nJ(\text{C-1, H})$ within glucose, ^{13}C -labeled at C-1, utilizing the pulse sequence shown in Figure 11(d). The heteronuclear couplings are read from the chemical shift difference between corresponding upper and lower multiplets. The digital resolution in the ω_2 domain is 0.055 Hz pt^{-1} , allowing the $^4J(\text{C-1, H-6R})$ and $^4J(\text{C-1, H-6S})$ couplings to be determined as 0.2 ± 0.05 and $0.4 \pm 0.1 \text{ Hz}$, respectively

The major disadvantage of this approach lies in the fact that weak, direct interactions are frequently obscured by indirect effects and, thus, escape observation. More recent studies are based on measurements of cross-relaxation rates between two nuclei. Values for these parameters can be obtained either from multiselective relaxation time measurements¹¹⁵ or analyses of 1D transient or 2D NOESY spectra.¹¹⁴ The cross-relaxation rates are extracted from NOESY experiments on the basis of the two-spin approximation¹⁸² or by ‘full relaxation matrix analysis’.¹⁸³ The latter method has proven to be the most reliable in conformational analyses of carbohydrates.⁶⁶ Selective 1D NOESY experiments can give accurate (within 3%) estimations for cross-relaxation rates in small and medium-sized oligosaccharides, even at long mixing times. Moreover, selective spectra are free from zero quantum interferences which particularly obscure analysis of 2D NOESY spectra at short mixing times. Another crucial issue in quantitatively analyzing NOE data lies in their avoidance of contamination by indirect magnetization transfers. Undesired three-spin effects can be eliminated by (multi-)selective irradiation of potential mediators of spin diffusion during the NOESY mixing time.¹⁸⁴

In order to overcome the problem of trying to detect vanishingly small NOE effects for tri- and tetrasaccharides at $\sim 400\text{--}500 \text{ MHz}$, a novel technique for measuring cross-relaxation rates in the rotating frame was proposed. After its first application to a tetrasaccharide,⁶³ the technique’s name was changed from CAMELSPIN to ROESY¹⁸⁵ spectroscopy and steadily gained the confidence of NMR spectroscopists as being an invaluable addition to the assortment of techniques used for the conformational analysis of molecules of all sizes. A major problem in the quantitative analysis of ROESY spectra are Hartmann–Hahn effects which occur in coupled spin systems.^{154, 186} These effects can, however, be minimized experimentally by a judicious choice of the carrier frequency.¹⁵⁴ An important feature of ROESY spectra is that NOE and chemical-exchange-mediated magnetization transfers

can be readily distinguished.^{187, 188} Sialyl- $\alpha(2\rightarrow6)$ -lactose, when investigated at 500 MHz and ambient temperature, is characterized by laboratory frame $^1\text{H}/^1\text{H}$ NOEs close to zero. Therefore, most of the distance constraints listed for the trisaccharide in Table 2 were obtained via 1D selective ROESY experiments.¹⁰⁶

4.2.2.5 Hydrogen Bonding. The detection of intramolecular hydrogen bonds requires the observation of chemical shifts, linewidths, temperature shift coefficients, NOEs, and, if possible, $^3J(\text{HOCH})$ couplings and exchange rates of assigned OH signals. In order to use OH protons as conformational probes for oligosaccharides, special techniques for water suppression must be utilized.^{157, 189–191} Additionally, isotope effects on ^{13}C chemical shifts examined in $\text{H}_2\text{O}/\text{D}_2\text{O}$ (1:1, v/v) may be interpreted in terms of hydrogen bonding.¹⁰⁴

If chemical exchange rates are of the same order of magnitude as the vicinal coupling constants, the assignment of hydroxyl protons on the basis of scalar correlation spectroscopy will not be possible. In these cases, assignments can be based on spatial proximities to the ring protons gained from steady-state NOE spectra [see Figure 10(c) for the pulse sequence]. This procedure requires, however, a good deal of caution, as spin diffusion and NOE enhancements mediated by chemical exchange could lead to erroneous assignments. In mixed solvents at temperatures well below 0°C , chemical exchange is often retarded to an extent that transient NOE techniques can be utilized. As may be expected, even at low temperatures, the $^3J(\text{HOCH})$ couplings for mono- and disaccharides obtained are found to be indicative of rotational averaging of the ‘dangling’ hydroxyl groups in most cases.¹⁰³ However, NOESY experiments performed on supercooled di- and trisaccharides strongly suggest that the majority of the intramolecular hydrogen bonds inferred from their crystal structures persist in solution.¹⁰¹

Most of the OH signals of sialyl- $\alpha(2\rightarrow6)$ -lactose, investigated in mixed solvent systems at temperatures as low as -12°C and in $\text{H}_2\text{O}/\text{D}_2\text{O}$ at 1°C , were assigned by 1D steady-state NOE experiments. Based on their linewidths and temperature shift coefficients (in conjunction with isotope shift effects observed in the ^{13}C spectra of the trisaccharide in $\text{H}_2\text{O}/\text{D}_2\text{O}$), three OH groups were found to be involved in intramolecular hydrogen bonds. First, Neu5Ac OH-8 is involved in an intrasidue hydrogen bond to the C-1 carboxyl group;⁹⁹ secondly, the hydrogen bond between Glc OH-3 and Gal O-5 is reminiscent of that found in lactose,¹⁰¹ both in solution and in the crystal structure. Finally, the hydrogen bond observed between Neu5Ac OH-7 and Glc O-3 is an example of a long-range structural constraint of great value in the construction of the preferred conformation of sialyl- $\alpha(2\rightarrow6)$ -lactose in aqueous solution. Modeling of the trisaccharide was based on 25 interresidue NMR constraints (Table 2). Analysis by MMC simulations^{106, 192} has shown that sialyl- $\alpha(2\rightarrow6)$ -lactose occurs predominantly in two families of conformers that differ in the ϕ angle around the $(2\rightarrow6)$ -linkage (-60° versus 180°). The average structure of the predominant ($>80\%$) family of conformers is depicted in Figure 16; it is the family stabilized by the three intramolecular hydrogen bonds.

4.2.3 Dynamics

The 3D structure of the disaccharide sucrose [$\text{Fru}\beta(2\leftrightarrow1)\alpha\text{Glc}$] (Figure 17), particularly the conformation of its glycosidic linkage, has been the subject of numerous investigations.

Figure 16 Stereo plots [ball-and-stick (b), Dreiding models (c), CPK models (d)] of the predominant conformer ('family I', Table 2) of sialyl- $\alpha(2\rightarrow6)$ -lactose (a) in aqueous solution as derived from NMR data.¹⁰⁶ The Neu5Ac O-7::H::Glc O-3 and Glc O-3::H::Gal O-5 hydrogen bonds are clearly visible

Data obtained on sucrose in the crystalline^{193,194} and solution states^{93,174,195} have led to uncertainties concerning the degree of rigidity of the linkage conformation in solution, thus posing the question whether it is the same as in the crystal structure. A great deal of effort was spent examining intramolecular hydrogen bonding^{196,197} and its effect, if any, on the overall conformation of sucrose in solution. McCain and Markley¹⁹⁸ were the first to measure ^{13}C T_1 relaxation times on sucrose as a function of the magnetic field strength. They realized the importance of knowing the timescale of internal motion when modeling carbohydrate conformations. As discussed in

Section 4.1.3, this information can, in principle, be gained from nuclear relaxation rate measurements, preferably at different field strengths and different temperatures. The number of such studies performed on carbohydrates is remarkably small, and a model rigid on the timescale of molecular reorientation is often assumed on the basis of ^{13}C T_1 relaxation times. Accordingly, McCain and Markley's careful ^{13}C T_1 measurements for sucrose revealed very fast and small amplitude torsional and vibrational motions^{198–200} and different mobility of exocyclic groups;²⁰⁰ however, the glycosidic linkage was judged to be rigid on the basis of this type of measurements, and similar in conformation to that observed in the crystalline state. Presenting a quantitative analysis of the field strength dependence of $^1\text{H}/^1\text{H}$ NOE data, Poppe and Van Halbeek¹⁰⁵ questioned the rigidity of the sucrose glycosidic bond in solution and explained the reasons why this type of flexibility was not revealed by McCain and Markley's data. The evidence is briefly reviewed below.

Seeking to reveal as large a set of interresidue distance constraints as possible and to shed light on the existence of any hydrogen bonds in sucrose in aqueous solution, sucrose was investigated at low temperatures in aqueous solutions with the purpose of including the OH signals in the analyses. All of the sucrose OH signals were indeed observed in 1–1 echo experiments [Figure 17(a)], and had lines sufficiently narrow to be assigned by 2D and selective 1D TOCSY experiments. To measure interresidue distance constraints, 1D ROESY [Figure 10(a)] and multiselective TOCSY–ROESY [Figure 10(d)] experiments were performed; these experiments benefited from the excellent water suppression by an inhomogeneous, transverse B_1 field [see Figure 17(b–f)]. The concept of selective 3D TOCSY–NOESY and TOCSY–ROESY spectroscopy [as mentioned for the assignment of the Gal H-6 protons in sialyl- $\alpha(2\rightarrow6)$ -lactose, Figure 13] was extended to include multiple selective excitations. In an analogous manner to a 1D NOE experiment, these experiments allowed the measurement of NOEs between H-5 g and its spatial neighbors, in addition to NOEs between H-1 g and its neighbors ('g' denotes the glucose, 'f' the fructose moiety in sucrose). An example of a double selective pseudo 3D TOCSY–ROESY spectrum of sucrose is shown in Figure 17(c). Selective excitation of the H-4 g resonance was followed by a TOCSY step, a second selective pulse applied to the H-5 g resonance, and finally a ROESY step. Thus, NOE connectivities originating from H-5 g, which could not have been excited in a single selective experiment, were successfully measured. Special care was taken to ensure that NOEs were free of spin diffusion artifacts before converting them into distances. The standard 1D NOESY spectrum of sucrose after selective excitation of the H-1 g resonance [Figure 18(a)] revealed NOE enhancements to H-11'f, H-66'f, H-4f, H-5f, and H-3f. To determine the amount of the H-1 g/H-3f NOE due to direct magnetization transfer, H-11'f, H-4f, and H-5f were selectively and simultaneously spin locked during the mixing time of a second experiment [Figure 18(b)], thereby cutting off all possible indirect magnetization transfer pathways from H-1 g to H-3f. The results of the quantitative NOE measurements are compiled in Table 3. Interestingly, all NOE connectivities (and the lone exchange interaction, see below) found for sucrose in water solution

Figure 17 500 MHz ^1H NMR spectra of sucrose [$\text{Fru}\beta(2\rightarrow1)\alpha\text{Glc}$; g = Glc, f = Fru] (5 mg in 0.5 ml of $\text{H}_2\text{O}/(\text{CH}_3)_2\text{CO}$, 6:1, v/v) obtained at -10°C (except trace f). (a) Spectrum obtained with a 1–1 echo pulse sequence. (b) 1D ROESY spectrum (320 scans) obtained with the pulse sequence shown in Figure 10(a); selective excitation of the H-1g resonance was followed by a 200 ms spin lock pulse train. (c) Double-selective 3D TOCSY–ROESY spectrum obtained with the pulse sequence shown in Figure 10(d). Selective irradiation of H-4g was followed by 30 ms of isotropic mixing, the selective irradiation of H-5g, and a 200 ms spin lock pulse train; 640 scans were accumulated. (d, e) 1D ROESY spectra (320 scans) with selective irradiation of OH-1f and OH-2g, respectively. (f) 1D ROESY spectrum, recorded at -6°C , with selective irradiation of OH-2g. A comparison of traces (e) and (f) reveals an OH-2g/OH-1f chemical exchange interaction, suggesting the existence of an O-1f::H::O-2g hydrogen bond in solution under the applied conditions¹⁰⁵

can be explained in terms of a single conformation, which is virtually identical to that in its crystal structure.

However, when measuring specific $^1\text{H}/^1\text{H}$ cross-relaxation rates as a function of magnetic field strength and temperature, large conformational changes occurring much faster than the overall motion were revealed around the glycosidic bond.¹⁰⁵ Selective excitation at the H-1g resonance was followed by the detection of NOEs at H-11'f, H-4f, and several protons in the glucopyranose ring. The NOEs between protons on different rings proved to be field-strength-dependent, while this did not seem to be the case for NOEs between protons in the glucopyranose ring [Figure 18(c)]. This observation is interpreted as evidence for the occurrence of rearrangements around the glycosidic bond between the glucosyl and fructosyl residue which are much faster than the tumbling time of the molecule in solution ($\tau_0 \sim 0.2$ ns). This type of internal motion is transparent

Figure 18 (a) 1D NOESY spectrum (500 MHz; $\tau_{\text{mix}} = 0.4$ s) of sucrose [$\text{Fru}\beta(2\rightarrow1)\alpha\text{Glc}$; g = Glc, f = Fru] in a $\text{D}_2\text{O}/(\text{CH}_3)_2\text{CO}$ (6:1, v/v) solution) at -5°C . The interresidue NOE enhancements of fructose ring protons obtained after selective excitation of Glc H-1 are indicated [see the pulse sequence in Figure 10(b)]. (b) Identical to (a), with the addition of the triple-selective spin locking of H-4f, H-5f, and H-11'f (marked with arrows) during the mixing time using a triple-DANTE pulse train. As all possible indirect magnetization transfer pathways from spin H-1g to spin H-3f are cut off in experiment (b), the measured H-1g/H-3f NOE enhancement is solely the result of direct dipolar interaction between these two spins. (c) Distances $r_{\text{H-1g-H-4f}}$ and $r_{\text{H-1g-H-11'f}}$ as determined from 1D NOESY and 1D ROESY measurements on sucrose in H_2O solution at two different temperatures (-1°C and 12°C) and four magnetic field strengths (250, 400, 500, and 600 MHz). Theoretical values for $r_{\text{H-1g-H-4f}}$ (dotted lines) were predicted from a model described by Poppe and Van Halbeek,¹⁰⁵ assuming rapid interconversion of three different rotameric conformations around the glycosidic linkage

Table 3 $^1\text{H}/^1\text{H}$ Distances for Sucrose in Aqueous Solution Derived from Interglycosidic NOE Contacts¹⁰⁵

Proton pair ^a	Distance ^b (Å)
H-1g/H-1f	2.6 ^c
H-1g/H-3f	4.6
H-1g/ H-4f	3.5 ^c
H-1g/H-6f	4.0
H-5g/H-4f	3.0
H-1g/OH-1f	3.6
H-1g/OH-6f	3.4
H-1g/OH-3f	4.0
H-5g/OH-3f	3.8
OH-2g/H-1f	3.2

^aData for aliphatic protons were acquired at 27 °C, data for hydroxyl protons at −10 °C; ‘g’ denotes the glucosyl, ‘f’ the fructosyl ring.

^bDistances were calculated using the formula $r_{ij} = (\sigma_{\text{ref}}/\sigma_{ij})^{1/6} r_{\text{ref}}$ in which σ_{ref} and r_{ref} represent the cross-relaxation rate of and the distance between a reference pair of protons. Intraglucosyl distances H-1g/H-2g (2.4 Å), H-1g/H-3g (3.7 Å), and H-1g/H-4g (4.0 Å) were used as references. The precision of the distances r_{ij} is estimated to be 0.1r.

^cSee Figure 18(c).

to relaxation parameters, including ^{13}C T_1 , if it occurs on the timescale of overall molecular tumbling; this seems to be the case for sucrose at ambient temperature. Thus, the accurate measurement of ^1H cross-relaxation rates ($\sigma_{\text{H,H}}$) has the following advantages over traditional ^{13}C T_1 measurements: (i) a higher spectral sensitivity; (ii) an increased ability to detect internuclear fluctuations; (iii) a dependence on spectral density at zero frequency and, therefore, sensitivity to slow motions, and (iv) the greater diversity of geometric orientations of the H–H vectors in a rigid pyranose ring, as compared with the parallel orientation of most of the C–H vectors, allowing more efficient sampling of spectral densities.

Additionally, the observation of chemical exchange between OH-1f and OH-2g [Figures 17 (e) and (f)] provides reasonable evidence for the existence of an OH-1f::O-2g hydrogen bond in solution under the applied conditions. In summary, it appears that intramolecular hydrogen bonding in sucrose is concentration-dependent; the existence of hydrogen bonds OH-1f::O-2g, OH-3f::O-2g, and OH-6f::O-5g at higher concentrations has been postulated, based inter alia on ^{13}C isotope effects.¹⁹⁶ The existence of the first two hydrogen bonds at high concentration in solution implies flexibility and fast interconversion between two conformers around the glycosidic linkage in solution (in the crystal only OH-1f::O-2g and OH-6f::O-5g are observed).

Once fast internal motion in sucrose was detected by measuring a number of interglycosidic NOEs as a function of magnetic field strength and temperature of the solution,¹⁰⁵ similar observations were reported for other di- and trisaccharides.^{201–204} It is now widely accepted that small oligosaccharides are flexible molecules, experiencing intramolecular rearrangements that are fast compared with the overall tumbling of the molecules.

4.3 Glycoprotein Oligosaccharides

Although, during the past decade, NMR spectroscopy has become sophisticated enough to handle conformational

analysis of glycoprotein-related oligosaccharides and glycopeptides in solution, few of these oligosaccharides have yet been examined as rigorously as the di- and trisaccharides mentioned in Section 4.2. In hindsight, the relatively slow pace in which oligosaccharide conformational analysis has developed is primarily due to glycobiologists’ expectations concerning the models for glycoprotein carbohydrates; they expected a single, rigid 3D shape for an oligosaccharide of any given primary structure. This school of thought was based on pioneering investigations of the ABH and Lewis blood group determinants [for primary structures see Figure 1(d)]. However, as it turned out later, these branched tri- and tetrasaccharide epitopes happened to be far more rigid than most small oligosaccharides, leading to the misguided concept of carbohydrate 3D structural rigidity and the resultant overconfidence that modeling of any carbohydrate could be handled by the HSEA approach (hard-sphere representation of nonbonded interactions dominated by the *exo*-anomeric effect). Most glycoprotein oligosaccharides are flexible to some degree and are continually experiencing dynamic fluctuations in structure. Their flexibility is important because it may allow them to fit into the binding sites of carbohydrate-binding proteins (lectins, antibodies, receptors) (Section 5.3). In chronological order, we will summarize the work on blood group oligosaccharides which are known to occur in the peripheral portions of glycoprotein and ganglioside carbohydrate chains, followed by more typical *N*-type and *O*-type glycoprotein carbohydrate structures (Figure 1).

4.3.1 Peripheral Epitopes

The conformations of blood group oligosaccharides were first investigated by Lemieux et al.,²⁰⁵ who reported ^1H and ^{13}C NMR assignments for trisaccharide fragments of the oligosaccharides denoted A, B, H, Le^x , and Le^y in Figure 1(d). Qualitative NOE data, along with primitive conformational energy calculations, were thought to indicate single conformations for each of these oligosaccharides. The influence of hydrogen bonding and other electrostatic effects was proposed to be unimportant; the rigid conformations were thought to be mainly determined by steric or nonbonded interactions and by torsional potentials.²⁰⁶

With the advent of more sophisticated NMR techniques, as well as a less naive approach to oligosaccharide modeling, Bush and co-workers set out to apply much more rigorous tests to these proposals in the late 1980s. This group of investigators acquired large collections of carefully measured NOE data on blood group and related oligosaccharides in various solvents at a number of sample temperatures.^{207–215} Full relaxation matrix analysis of those data, along with MD simulations, revealed that the blood group epitopes found on glycoproteins and glycolipids assume relatively rigid conformations. The latest results obtained by Bush and co-workers on the Le^x trisaccharide and sialyl- Le^x tetrasaccharide^{208,216} indicate that the Le^x portions of the molecules are rigid, but the Neu5Ac α (2→3)-linkage shows transitions between two predominant conformational states [experimentally defined by ROE and $^3J(\text{C,H})$ values]. Other investigators^{217,218} concur with these findings on the issue of the rigidity of the Le^x portion of the molecule [i.e., the conformation can be described by one set of ϕ, ψ -values for the Fuc α (1→3)GlcNAc and Gal β (1→4)GlcNAc linkages each] and support a model featuring fast exchange between two different conformations

of the Neu5Ac α (2 $\rightarrow$ 3)Gal-linkage. The dynamics of fucosyl- α (1 $\rightarrow$ 2)-lactose and related oligosaccharides are currently being reinvestigated along the lines discussed in Section 4.2^{203,204}

4.3.2 *N*- and *O*-Type Glycoprotein Oligosaccharides

The NOE-based conformational analysis of *N*-type glycoprotein oligosaccharides began simultaneously and independently in Toronto^{219–222} and Oxford.²²³ The conformations of the various linkages in the diantennary *N*-acetylglucosamine-type oligosaccharide [Figure 1(b)] and its high-mannose analogs were evaluated and, at first, judged to be fairly rigid with the exception of the α (1 $\rightarrow$ 6)-linkage. In 1987, however, both the Toronto^{224–226} and the Oxford^{227–229} groups realized that they had proposed ‘virtual conformations’ for the *N*-type core structures up to that point. When carefully scrutinized, the increased amount of NOE constraints available at that time appeared to be inconsistent with one conformation per linkage and prompted a reevaluation of the concept of carbohydrate structure rigidity. The ensemble representation was introduced for the oligosaccharides, as NMR observables calculated as ensemble averages gave better agreement with experimental values than those derived from single structures. Since then, MD simulations and NOE measurements at different field strengths have been helping each other over a number of ‘barriers’ to the further understanding of glycoprotein carbohydrate dynamics. Both the Oxford and the Toronto groups have recently resorted to small di-, tri- and tetrasaccharide building elements of the *N*-type oligosaccharides in order to assess carefully their dynamic behavior, while simultaneously attempting to improve the molecular modeling methods for carbohydrates.^{76,107,108,201,230–234} Currently, detailed NMR studies on larger *N*-type oligosaccharides covalently linked to proteins are being conducted as well (Section 5.1). Impartial review articles^{18,66,83,235} keep the glycobiology community abreast of continuing developments in this area of research.

Additional insight into the conformation of the core pentasaccharide Man₃GlcNAc₂ in an *N*-type glycopeptide was provided by a study of a hen ovomucoid glycodecapeptide.²³⁶ TOCSY and NOESY experiments on the glycopeptide in H₂O, supported by ³*J*(N,H) data, provided evidence that the C-2–N-2 bond in Asn-linked GlcNAc is rigid; however, this rigidity could not be attributed to any intramolecular hydrogen bond. Although these and other sophisticated tricks of the NMR trade are just beginning to be applied to larger oligosaccharides and glycopeptides, we now have a reasonable picture of the conformation and flexibility of *N*-type oligosaccharides of the high-mannose and the *N*-acetylglucosamine type. Similar investigations of *O*-type Ser/Thr-linked oligosaccharides^{78,237,238} and small sialyl oligosaccharides (Section 4.2) are currently being conducted. Given the similarities of the backbone and peripheral structural elements of *N*-type and *O*-type oligosaccharides, the results should be applicable to both classes of glycoprotein carbohydrates.

4.4 Glycolipids and Glycolipid-Related Oligosaccharides

Oligosaccharides released from gangliosides and other glycolipids (by endoglycoceramidase digestion or ozonolysis) are amenable to, and have been investigated by, the same NMR

Figure 19 Subspectral editing of the ¹H NMR spectrum (600 MHz) of the GD_{1a} oligosaccharide in D₂O [16 mg mL^{−1}] by 1D TOCSY [see the pulse sequence in Figure 10(a)]. The H-1 signals of the hexosyl residues and the H-3ax signals of the Neu5Ac residues, respectively, were selectively excited. Superscripts in Gal³ and Gal⁴ refer to the position of the linkage in which these residues are involved (ext = external; int = internal). The constant isotropic mixing time was 370 ms; 160 scans were accumulated per spectrum

techniques as mentioned for glycoprotein oligosaccharides (Section 4.3). For example, the 1D TOCSY subspectra of the Gal and Neu5Ac residues in the GD_{1a} oligosaccharide (Figure 19) serve to illustrate that, despite the abundance of small couplings, magnetization can be propagated over the entire spin system of each residue allowing the complete assignment of these spectra. The conformations of the oligosaccharide portions of gangliosides such as GM₁, GM₂, GD_{1a} (for primary structures, see Figure 1), and GPI anchors^{239,240} have been studied in aqueous environments by ¹H/¹H NOESY methods in combination with molecular modeling.^{241,242} Frequently, the results obtained on the free oligosaccharides have been compared to those obtained by examinations of the intact glycolipids in DMSO solutions and other aprotic solvents.^{51,55–57,64,187,188,243–247} In particular, the study of peripheral blood group elements which are so abundant on glycolipids features prominently in this work; not unexpectedly (see Section 4.3.1), the conformations of these epitopes are independent of the solvent. Although the results of these studies in DMSO are interesting from a basic science point of view, we will not review their details because of their relative lack of biological significance. Instead, we will turn to micellar systems formed by glycolipids in aqueous solutions (Section 5.2), emulating the cell’s plasma membrane, and compare the carbohydrate’s structures under those circumstances to the structures of the free glycolipid oligosaccharides in water.

Due to the relative ease with which they can be ^{13}C -enriched, glycolipids have recently inspired the development of several new NMR spectroscopic techniques. Heteronuclear 3D NMR experiments, employing ^{13}C chemical shift editing of homonuclear correlation spectra, are an effective means of reducing spectral overlap for larger carbohydrates, particularly when ^{13}C -enriched carbohydrates are available for investigation.^{235,248} Complete ^1H assignments for uniformly ^{13}C -labeled carbohydrates have been obtained with the use of HCCH-COSY and HCCH-TOCSY experiments.²⁴⁹ By employing the $^{13}\text{C},^{13}\text{C}$ coupling pathway [$^1J(\text{C},\text{C}) \sim 40\text{ Hz}$] for magnetization transfer, these techniques overcome the T_2 relaxation [$^3J(\text{H},\text{H}) \ll \text{linewidth}$] problems observed in $^3J(\text{H},\text{H})$ -mediated $^1\text{H},^1\text{H}$ COSY and TOCSY spectra of glycoconjugates of high molecular weights and yield well-resolved spectra for polysaccharides and glycolipids. The 2D constant evolution time HCCH-COSY and HCCH-TOCSY experiments are particularly useful for the study of carbohydrates due to the relatively constant value of $^1J(\text{C},\text{C})$ couplings around the carbohydrate ring (36–45 Hz) which facilitates optimization of the fixed delay for $^{13}\text{C},^{13}\text{C}$ magnetization transfer. The resulting $^{13}\text{C},^{13}\text{C}$ decoupling simplifies the analysis of the ^1H spectra as traces in the 2D plots. Alternatively, ^1H -detected $^{13}\text{C},^{13}\text{C}$ COSY experiments may be performed for complete ^1H and ^{13}C assignments of ^{13}C -enriched oligosaccharides (as was illustrated for the uniformly ^{13}C -labeled carbohydrate headgroup in a sulfolipid²⁵⁰). The sensitivity and resolution of the ^1H -detected 3D ^{13}C COSY experiments can be considerably improved by the implementation of pulsed field gradients, as demonstrated for a digalactosyl diacylglyceride which was biosynthetically uniformly ^{13}C -enriched to $\sim 15\%$.²⁵¹

5 THE FUTURE: GLYCOCONJUGATES IN (INTER-)ACTION AT THE MEMBRANE SURFACE

The molecular behavior of an oligosaccharide chain isolated from a glycoprotein or glycolipid differs considerably from the behavior of the chain when bound to a protein or lipid. For example, the molecular motion of a freely tumbling oligosaccharide will be substantially different from that of the same oligosaccharide anchored to a protein backbone and/or in a lipid bilayer. It is quite conceivable that both molecular conformation and internal dynamics are affected upon the covalent binding of an oligosaccharide to a protein. Thus, appropriate caution must be exercised when extrapolating NMR-derived results concerning conformation and dynamics of isolated oligosaccharides to similar structures linked to proteins or lipids. NMR efforts are now underway to examine the conformation and dynamics of oligosaccharides as covalent parts of larger molecular weight glycoconjugates, both intact glycoproteins (Section 5.1) and glycolipids dispersed in lipid bilayers (Section 5.2). Also, the study of noncovalent carbohydrate-protein interactions via NMR methods is producing its first encouraging results (Section 5.3).

5.1 Glycoproteins

It has been known for quite some time²⁵² that the ^{13}C NMR spectra of intact glycoproteins in solution display signals arising from the oligosaccharide component that are considerably

sharper than those arising from the polypeptide backbone. This observation suggests that the oligosaccharides of at least some intact glycoproteins possess motional characteristics other than those conferred on them by the tumbling of the protein; in other words, local (segmental) motion is experienced by the oligosaccharide chain. In 1982, Goux et al.²⁵³ reported on ovalbumin in which nonreducing Gal was enriched in ^{13}C . Off-resonance rotating frame relaxation data showed that the carbohydrate had a 40–80 ps motion superimposed on the slow overall tumbling ($\tau_o \sim 25\text{ ns}$) of the protein.

Several NMR studies are currently being designed to elucidate the conformational effects of covalently linked carbohydrates on peptides in glycoproteins and vice versa. The glycoprotein ribonuclease B (RNase B) has most often served as the ‘guinea pig’. The consensus with regard to this glycoprotein and several others seems to be that oligosaccharide and peptide do not mutually affect each other’s conformation; instead, the oligosaccharide causes a decrease in the peptide’s conformational mobility near the glycosylation site and vice versa. Thus, mutual effects have been observed on the local dynamics of peptide and oligosaccharide rather than on their conformation per se. For example, NMR measurements of amide H/D exchange rates on RNase A and B revealed that glycosylation of the protein leads to the protection of amide proton resonances from solvent exchange for a large number of amino acid residues in the vicinity of the glycosylation site and in more remote locations.^{254,255} The detailed influence of a high-mannose oligosaccharide on the enzyme’s properties was also explored with a combination of MD simulations of the carbohydrate, employing a novel force field parameterization for glycoproteins (GLYCAM-93), and structural model building based on the 2.5 Å X-ray crystal structure of the enzyme;²⁵⁶ the results are currently awaiting NMR experimental verification.

Studies^{108,231} focusing on the local dynamics of the $\text{Man}_5\text{GlcNAc}_2$ carbohydrate chain in RNase B took advantage of the protein’s presence; the protein is, in essence, a large mass which, relative to the timescale of the internal motions, tethers the reducing end of the glycan. This causes the relaxation parameters to become much more sensitive to differential motion along the glycan chain. In addition, the overall motion of the glycoprotein can be considered to be isotropic, considerably simplifying data analysis. The order parameter S^2 was measured for reorientation of the C-1–H-1 vector of each glycosyl residue. As computed from ^{13}C T_1 values, S^2 was found to be ~ 0.5 for internal residues and ~ 0.1 for terminal residues (most distal to the protein). The rate of internal motion was found to be an order of magnitude higher for the distal than for the proximal residues. These data strongly support the existence of significant torsional oscillations about glycosidic bonds in high-mannose oligosaccharides.

However, there is at least one well-characterized glycoprotein in which carbohydrate and protein conformation do affect each other considerably: the F_c fragment of immunoglobulin G (IgG) containing an *N*-linked carbohydrate chain at Asn₂₉₇ in the hinge region. There is compelling evidence, both from X-ray structural data and molecular modeling,^{77,257} that the (1→6)-arm of the diantennary oligosaccharide interacts with Phe₂₄₃, Pro₂₄₄, and Thr₂₆₀ residues of the protein. These interactions result not only in the loss of the flexibility associated with the (1→6)-arm, but also in a conformation of the

diantenna very different from that of the free oligosaccharide in solution. Recently, the F_c fragment in which ^{13}C -labeled Gal had been biosynthetically incorporated in terminal position of both arms of the diantenna in a similar way to the aforementioned studies on ovalbumin, was probed by ^1H -detected ^{13}C , ^1H NMR. The two Gal residues were distinctly different in their NMR parameters (chemical shifts, linewidth), providing evidence for the strong interaction in solution of one arm of the diantenna with the peptide backbone.

5.2 Dynamics of Membrane-Bound Carbohydrates

Due to their amphipathic nature, isolated glycolipids aggregate in aqueous solution to form micelles. With their long overall rotational correlation times, these systems lend themselves to high-resolution NMR studies and are the most revealing probes currently used for the study of internal motions in lipid-linked oligosaccharides. Poppe and co-workers have studied the conformation and dynamics of the carbohydrate headgroups of a number of glycolipids inserted in deuterated dodecylphosphocholine (DPC) micelles in D_2O and/or H_2O , including globoside,^{129,187} Forssman antigen,¹⁶² and the gangliosides GM_4 ,²⁵⁸ GM_3 and Neu4Ac5Gc-GM_3 ,²⁵⁹ GM_1 ,¹⁸⁸ and GD_{1a} .²⁶⁰ The researchers typically measured interglycosidic $^1\text{H}/^1\text{H}$ NOEs and used these to build tentative 3D structures of the oligosaccharide using a distance mapping procedure.¹⁸⁸ Figure 20 shows 1D NOESY spectra for one of the galactose residues in the GD_{1a} ganglioside/micelle system in D_2O solution. Selective spin locking during the mixing time, obtained with a double-DANTE pulse sequence,²⁶¹ allowed the calculation of, for example, the intraring Gal H-1–H-4 distance based upon a spin-diffusion-free NOE effect.

Figure 21 shows that GD_{1a} in a micellar membrane in H_2O is singularly suited for high-resolution NMR studies, particularly those focusing on its OH signals at low temperature, without the use of organic solvents. It appeared²⁶⁰ that the observed NOEs could not be explained by the occurrence of the GD_{1a} oligosaccharide in a single conformation such as the reasonably rigid structures proposed for the GD_{1a} -free oligosaccharide²⁴² in D_2O and glycolipid²⁴⁵ in DMSO on the basis of ^{13}C T_1 data. At least two families of carbohydrate conformers, differing in the relative orientation of the $\text{Neu5Ac}\alpha(2\rightarrow3)\text{Gal}\beta(1\rightarrow3)$ external disaccharide arm, must exist in this model membrane system to account for the NOE constraints. The internal dynamics of the oligosaccharide were probed by ^1H detection of the ^{13}C relaxation parameters (T_1 , $T_{1\rho}$, and heteronuclear NOEs) of the micellar system at ^{13}C natural abundance. The internal reorientations were found to occur with a rotation correlation time of 0.35 ns. The slow tumbling of the micelle ($M_r \sim 8\text{ kDa}$) provided the distinct timescale ($\tau_o = 2.8\text{ ns}$), facilitating the discovery of the faster internal motion of two flexible glycosidic linkages in the carbohydrate headgroup.²⁶⁰

Applications of these methods to larger complex oligosaccharides, as well as to those tethered to proteins or lipid membranes, will continue to provide valuable evidence with which to address the question of internal motions on a timescale of the reciprocal of the NMR frequency range used in the experiment (0.1–1 ns). Motions on a slower timescale, which would not be detectable by ^{13}C T_1 experiments, can be studied with rotating frame relaxation data ($T_{1\rho}$). With control of the spin

Figure 20 1D NOESY spectra (600 MHz, 25 °C) of $\text{GD}_{1a}/\text{DPC-}d_{38}$ micelles in D_2O solution. Mixing time 0.4 s. (a) Selective irradiation of Gal^3 H-1. The labels indicate intraresidue NOEs that are significantly compromised by spin diffusion. (b) Selective irradiation of Gal^3 H-1 with double-selective spin locking of Gal^3 H-3 and H-5 during the mixing time. The resulting H-1/H-4 NOE intensity is devoid of indirect magnetization transfers

locking field strength, the latter parameter can reveal motions on the μs timescale.

Alternative approaches to unmasking the conformation and dynamics of glycolipids embedded in model membranes include the study of the angular dependence of NOE in oriented systems of GM_3 ganglioside with partially ^{13}C -labeled sialic acid²⁶² at the surface of magnetically oriented membranes. Dipolar interactions measured between ^{13}C , ^{13}C and ^{13}C , ^1H pairs located in the ^{13}C -labeled sialic acid moiety of GM_3 are interpreted as indications that the GM_3 structure is well extended from the membrane surface. In fact, membrane-bound GM_3 was shown to bind wheat germ agglutinin (WGA), leading to the conclusion that the dominant GM_3 structure at the membrane surface is favored for binding by the lectin. These and other aspects of NMR studies of glycolipids at model membrane surfaces are covered in detail by Jarrell (*Glycolipids*) in this Encyclopedia.

5.3 Carbohydrate–Protein Interactions

The general argument made in Section 2 for the role of complex carbohydrates as informational macromolecules implies that there must be a mechanism for decoding the information which is stored in their structures. Apparently, this decoding depends on a group of multivalent carbohydrate-binding proteins known as (se)lectins. Lectins are widely distributed in animal tissues (albeit in small quantities) and bind simultaneously to at least two carbohydrate determinants (epitopes). Some lectins are membrane-bound, others are soluble; both are thought to function by facilitating communication between

Figure 21 ^1H NMR spectra of $\text{GD}_{1\text{a}}$ /DPC- d_{38} micelles in aqueous solutions; (bottom trace) spectrum in D_2O at 22°C ; (top trace) spectrum in 90% H_2O /10% D_2O at 0°C , obtained with the 1–1 echo water suppression technique. The experimental data obtained on the micellar $\text{GD}_{1\text{a}}$ system are compatible with the existence of two conformations of the external Neu5Ac–Gal portion of the oligosaccharide relative to the core tetrasaccharide anchored into the micelle. Interconversion between the two conformers is fast ($\tau_i = 0.35$ ns; $S^2 = 0.55$ for the external disaccharide unit) relative to the overall tumbling of the micellar system ($M_r \sim 8$ kDa; $\tau_o = 2.8$ ns; $S^2 = 1$)²⁶⁰

cells by linking them together. Antibodies are another class of soluble proteins involved in biological interactions with carbohydrates.

NMR spectroscopy is beginning to emerge as an experimental approach to the study of carbohydrate–protein interactions. Although limited by the size (molecular weight) and solubility of the protein, NMR spectroscopy is particularly useful for detailed studies of protein–carbohydrate interactions in solution when the complex has a molecular weight less than 35 kDa; under favorable circumstances, NMR can provide information about larger molecular weight systems as well. In general, if detailed information about conformation is sought, it is preferable that the ligand or the protein be ^{15}N , ^{13}C and ^{13}C , ^{15}N doubly labeled in order to provide a sufficient amount of structural constraints. For the larger M_r protein–carbohydrate complexes this is a necessity; for the smaller M_r complexes it is highly desirable (cf. Otting²⁶³).

NMR spectroscopic studies on the interactions between proteins and carbohydrates have focused on several systems, including the lectins wheat germ agglutinin^{264,265}, concanavalin A, *Sambucus nigra* agglutinin, *Ricinus communis* B,¹²² and *Aleuria aurantia* agglutinin²⁶⁶ with their respective ligands, and several monoclonal antibodies with their oligosaccharide antigenic counterparts.^{267–269} The typically weak carbohydrate–protein binding and intermediate-to-fast exchange between the free and the bound ligand permit transferred NOE (TrNOE) studies^{108,263,270,271} and lineshape analysis. The aim of a TrNOE experiment is to measure *negative*

Figure 22 (a) The 500 MHz ^1H NMR spectrum of sialyl- α (2 $\rightarrow$ 3)-lactose [5 mM in $\text{H}_2\text{O}/(\text{CD}_3)_2\text{CO}$, 8:1, v/v] obtained at -12°C with the 1–1 echo water suppression technique. Among the OH signals, the Neu5Ac OH-8 signal is characterized by the smallest exchange contribution to the linewidth and the smallest temperature variation of chemical shift (~ 0.001 ppm $^\circ\text{C}^{-1}$). (b) 1D pre-steady-state NOE difference spectrum obtained subsequent to presaturation of OH-8 under the conditions described in (a); a strong NOE contact to Neu5Ac H-6 is observed. (c) 1D clean-ROESY²⁷² spectrum of sialyl- α (2 $\rightarrow$ 3)-lactose (5 mM in D_2O , 25°C , 600 MHz). (d) 1D transferred NOESY spectrum of sialyl- α (2 $\rightarrow$ 3)-lactose in complex with wheat germ agglutinin (4 mM trisaccharide; 0.08 mM WGA; pD = 7, D_2O , 25°C , 600 MHz). Note the absence of an NOE between GalH-3 and Neu5Ac H-3ax in trace (d) while Neu5Ac H-8 experiences a NOE, suggesting that the conformation of sialyl- α (2 $\rightarrow$ 3)-lactose that binds to WGA is the less populated¹²⁹ conformation free in solution (conformation B; middle right)

NOEs on easily detectable free or averaged carbohydrate resonances following the irradiation of other carbohydrate resonances in order to obtain conformational information on the *bound* ligand. The true advantage of studying TrNOEs is that the effect is not restricted by the M_r value of the complex; instead, it continues to be favorable as the protein size increases. The TrNOE experiment is one of the few experiments capable of yielding information on the conformation of bound ligands in complex with large-size proteins. In general, the amount of information gained about the system will not be as large as from ^{13}C -labeled systems in the tight-binding/slow-exchange regime, and extreme care must be given to the analysis of the NOE-derived distances. For exchange rates $>100\text{ s}^{-1}$, one can analyze the data with relative ease; for rates between $10\text{--}100\text{ s}^{-1}$, the use of an extended relaxation matrix is necessary, as was demonstrated for the analysis of the binding of β -methylmelibiose to ricin B.¹²² The lectin preferentially selects one of the two conformations that melibiose adopts when free in solution. Similarly, WGA preferentially binds one of the two major conformations that sialyl- $\alpha(2\rightarrow3)$ -lactose adopts around the Neu5Ac-Gal linkage when free in solution. A preliminary TrNOE study of WGA isolectin 1 in complex with sialyl- $\alpha(2\rightarrow3)$ -lactose (Figure 22) suggests that conformation B is the one which preferentially binds to the lectin, in accordance with the crystal structure of the complex of WGA isolectin 1 with sialyl- $\alpha(2\rightarrow3)$ -lactose.²⁷³ More detailed studies are in progress to confirm this hypothesis. The studies follow the protocol of a recent NMR and X-ray study of the complex of a monoclonal antibody with a branched trisaccharide epitope.²⁶⁹ For this complex, Bundle and co-workers measured NOE build-up rates from TrNOE experiments which show that the trisaccharide undergoes a protein-induced conformational shift around a specific glycosidic linkage when bound in solution. Distance constraints derived from the TrNOE studies are consistent with two bound trisaccharide conformations, one of which correlates with the ligand conformation in the crystalline trisaccharide-antibody complex.

6 CONCLUSIONS

Since its first application to monosaccharide derivatives in the late 1950s, NMR spectroscopy has greatly contributed to our current knowledge of the structures and functions of complex carbohydrates. The importance of oligosaccharides in their own right and as the 'business ends' of glycoconjugates are becoming increasingly appreciated, and the role that NMR has played in this accomplishment cannot easily be overestimated. First of all, NMR spectroscopy provides a powerful nondestructive means with which to characterize the primary structures of carbohydrates and has, therefore, become an integral part of the current methodology of protein glycosylation site mapping. Moreover, the vast potential of NMR to unravel 3D carbohydrate structures and dynamics, as well as to study carbohydrate-protein interactions, is just beginning to penetrate into the collective mind of the glycobiology community. At the same time, NMR spectroscopists long preoccupied with the study of protein-peptide and protein-nucleic acid interactions are beginning to see the merits of investigating protein-carbohydrate interactions. Biological data point to a pivotal function for glycoproteins in the control of growth and

differentiation in the complex cell organization of eukaryotic systems. In fact, some complex oligosaccharides are implicated as onco-fetal antigens. Thus, the biological function of the complex carbohydrate chains of glycoproteins and glycolipids in animals is perhaps one of the most interesting unanswered fundamental questions in modern biochemistry. Unmasking carbohydrate structure-function relationships has been marked as the next frontier in molecular biology; the glycobiology community now finds itself turning to NMR spectroscopy to provide the instrumental means with which to enter this 'promised land'.

1 INTRODUCTION

Why is there a need for metal substitution? This approach in the investigation of metalloproteins has been, and is being, widely used in order to exploit the favorable spectroscopic properties of a suitable metal ion.^{1–6} With regard to NMR, paramagnetic metal ions are used because they produce additional contributions to both the shift and relaxation parameters of the nuclei coupled to them^{7–9} (see *Electron–Nuclear Hyperfine Interactions, Electron–Nuclear Multiple Resonance Spectroscopy*). The effect on the shift can be of sufficient size that, under certain circumstances, the signals due to such nuclei are well resolved from those of the rest of the protein. This increases the spectral resolution for those nuclei coupled with the paramagnetic center and, when the latter is in the active center of the molecule, very valuable biochemical information can be obtained.

Paramagnetic metal ions can be exploited as relaxation probes or shift probes depending essentially on their electron relaxation times. When the electron relaxation times are long, NMR lines are broad and the metal ion acts as relaxation probe (see *Paramagnetic Relaxation in Solution*). When electron relaxation times are short, NMR lines are relatively sharp and the metal ion acts as a shift probe. We are only interested in shift probes here.

In order to have little line broadening, the coupling between the electron spin S and the nuclear spin I should be modulated by correlation times τ_c in the range 10^{-11} – 10^{-13} s, depending on the number of unpaired electrons. As the rotational correlation times, τ_r , in macromolecules with molecular weights in the range 6000–50 000 are of the order of 10^{-8} – 10^{-9} s, it follows that the possibility of obtaining high-resolution NMR spectra depends on the efficiency of the electron relaxation of the metal ion.

If a diamagnetic metal ion (typically Zn^{2+} but also Ca^{2+} , Cd^{2+}) or a paramagnetic metal ion with unfavorable relaxation

properties (Cu^{2+} , Mn^{3+} , Mn^{2+} , high-spin Fe^{3+}) is present in a metalloprotein, its replacement with another metal ion with a similar ionic radius and similar coordination properties but favorable electron relaxation times gives rise to a metal-substituted protein whose metal ion surroundings can be investigated by NMR. Because of their favorable electronic properties with respect to NMR and their coordination chemistry, high-spin Co^{2+} and Ni^{2+} are among the most used and most suitable metal ions for substituting other metal ions, particularly Zn^{2+} . They are always high spin in tetrahedral geometry and, for Ni^{2+} , in octahedral geometry. Penta-coordinate ions are often high spin with oxygen and nitrogen donor atoms. In addition, octahedral Co^{2+} is often high spin.

The goal in the use of metal substitution is that of obtaining local information on the metal site through the analysis of the hyperfine (paramagnetic) shifts and of the nuclear relaxation rates of the nuclei of the metal ion ligands and of nearby residues. Furthermore, in the presence of inhibitors and pseudosubstrates, the NMR parameters provide information on the rearrangements induced by the binding of the molecule to the protein.

2 THE ELECTRONIC PROPERTIES OF HIGH SPIN COBALT(II) AND NICKEL(II) IONS

The Co^{2+} ion is a d^7 metal ion, the free ion having the ground state ^4F . In octahedral symmetry the ground state splits into $^4\text{T}_{1g}$, $^4\text{T}_{2g}$, $^4\text{A}_{2g}$, the ground state being $^4\text{T}_{1g}$. In the presence of low-symmetry components, spin–orbit coupling provides six Kramers doublets which are slightly separated. Conversely, in tetrahedral symmetry the ground state is the nondegenerate $^4\text{A}_2$ state. Hence, in O_h symmetry, low energy levels are available while in T_d symmetry the ground state is nondegenerate and excited levels are higher in energy. The presence of low-lying excited states in octahedral symmetry, arising from the splitting of the $^4\text{T}_{1g}$ ground level due to low-symmetry components, contributes to making electron relaxation more efficient in this geometry with respect to tetrahedral coordination and hence to shortening the electron relaxation times. Consequently, the τ_s values of a metal ion are dependent on the coordination geometry of the metal ion itself. For Co^{2+} , τ_s values of 10^{-13} – 10^{-12} s have been found for hexa-coordinate ions, of around 10^{-12} s for penta-coordinate, and of around 10^{-11} s for tetrahedral chromophores.⁹

In the case of the Ni^{2+} (d^8) metal ion, the splitting of the free ion term ^3F provides a nondegenerate ($^3\text{A}_{2g}$) ground state for octahedral chromophores and, therefore electron relaxation mechanisms are not very efficient. In contrast, in tetrahedral chromophores a degenerate ($^3\text{T}_2$) ground state is available and therefore more efficient electron relaxation pathways are operative. Thus τ_s values of 3×10^{-12} s have been estimated for $\text{Ni}(\text{H}_2\text{O})_6^{2+}$ ⁹ while tetrahedral Ni^{2+} experiences τ_s values in the range 10^{-12} – 10^{-13} s at low magnetic fields. As a consequence, Ni^{2+} is a better probe for metal substitution in tetrahedral systems, while Co^{2+} is more suitable for penta- and hexa-coordinate chromophores. In the next sections we will provide examples of metalloproteins in which the native metal ion has been replaced with Co^{2+} and/or Ni^{2+} and we will illustrate the valuable information thus obtained.

3 METAL SUBSTITUTION AND NMR PARAMETERS

One large and relevant class of metalloproteins is that of the zinc enzymes^{1–3} (see *Carbonic Anhydrase*; *Zinc Fingers*). Due to the similar coordination properties of the two metal ions, in many cases the cobalt(II)-substituted zinc proteins retain most of the biological properties of the native protein. Usually, substitution with Ni²⁺ produces derivatives with reduced biological activity. In addition, Fe²⁺, Mn²⁺, and Cu²⁺ have been replaced by Co²⁺ and also sometimes by Ni²⁺.^{6,10}

The extent of hyperfine shifts on the nuclei of residues directly bound to the paramagnetic metal ion depends on the metal ion itself and on the nature of the ligands (see *Electron–Nuclear Hyperfine Interactions*). The contact contribution is related to the spin delocalization on the ligand nuclei, while the pseudocontact contribution depends on the magnetic susceptibility anisotropy of the metal ion which, in turn, is determined by the nature of the metal ion and by its coordination geometry. Table 1 reports the range of observed chemical shifts for protons of various ligands to cobalt(II) and nickel(II) in different coordination geometries and in biological molecules. In a few cases the two contributions, i.e. contact and pseudocontact contributions, have been factored out. However, for the nuclei of ligands directly coordinated to the metal ion, the contact contribution is, by far, the dominant. From Table 1, it appears that shifts of up to +300 ppm have been observed for the H- β protons of cysteines coordinated to Co²⁺ and Ni²⁺.

The pseudocontact contribution to the shift in penta- and hexa-coordinate Co²⁺ chromophores is considerably larger than in tetrahedral coordination. The opposite occurs for Ni²⁺, where large pseudocontact shifts are observed for tetrahedral coordination and negligible pseudocontact contributions are observed in hexa-coordinate systems. The presence of sizable pseudocontact contributions to the shift causes the appearance of several relatively sharp resonances in the +25 to –20 ppm region of penta- and hexa-coordinate Co²⁺ systems arising from protons up to 7–8 Å apart from the metal ion and not belonging to metal-coordinated residues. The hyperfine shifted signals can be investigated via 1D NOE (see *Nuclear Overhauser Effect*) and/or 2D NMR spectroscopy in order to assign them unambiguously.

The increase in the nuclear relaxation rates due to coupling with the paramagnetic metal center occurs essentially through dipolar coupling for protons, while contact coupling can also appreciably affect nuclear relaxation in the case of other nuclei. In macromolecules, in the absence of chemical exchange, both couplings are modulated by the electron correlation times of the paramagnetic center.

A limitation in the application of high-resolution NMR in cobalt(II)- and nickel(II)-substituted proteins arises from the occurrence of substantial line broadening with increasing magnetic fields. Indeed, the contribution to transverse relaxation due to coupling of the nuclei with the static magnetic moment (Curie spin relaxation) (see *Paramagnetic Relaxation in Solution*) must be taken into account.¹¹ This contribution can be relevant in metalloproteins, and its relevance increases with the number of unpaired electrons and, consequently, with the magnetic moment of the metal ion.⁹ The spin state $S = \frac{3}{2}$ of cobalt(II) produces a sizable Curie spin relaxation contribution to the linewidth at high magnetic fields. The Curie spin relaxation term is modulated by τ_r and, therefore, increases with increasing molecular size. Furthermore, it depends on the square of the magnetic field. Hence, in unfavorable cases, i.e. large molecules at high magnetic fields, this contribution easily dominates transverse relaxation. As an example, consider a cobalt(II)-substituted protein of molecular weight 30 000 with τ_r of 1×10^{-8} s and a τ_s value of 5×10^{-12} s for Co²⁺. For a proton 5 Å from the metal ion, the overall (dipolar + Curie) linewidth at 200 MHz is 78 Hz and the Curie spin contribution is 28 Hz (i.e. the latter accounts for 37% of the overall linewidth). At 600 MHz the overall linewidth for the same proton is 293 Hz and the Curie contribution is 249 Hz (85% of the overall linewidth). This example shows why, due to the strong field dependence of signal linewidths in cobalt(II)-containing proteins, the use of lower field spectrometers can be convenient and, sometimes, necessary.

The ¹H NMR spectra of an inhibitor (thiocyanate) adduct of cobalt(II)-substituted carbonic anhydrase (molecular weight, 32 000) (see later), shown in Figure 1 at different magnetic fields, provide a nice example of the above considerations. It can be seen, for example, that signal A' is only detectable at 90 MHz, while signal E is still observable at 200 MHz but is broadened beyond detection at 600 MHz.

Two-dimensional experiments have been carried out on several cobalt(II)-substituted and nickel(II)-substituted macromolecules (see *Multidimensional Spectroscopy: Concepts*), despite the presence of a paramagnetic center (see later for examples). In these experiments the mixing times were relatively short with respect to the relaxation of the nuclei but long enough such that transfer of magnetization or coherence occurred. The recycle times can also be set to be relatively short in order to increase the number of transients in the experiment time, thus improving the signal-to-noise ratio.

Recently, it has been pointed out¹² that cross correlation between dipolar relaxation and Curie spin relaxation [which can be sizable in cobalt(II)-containing macromolecules] can

Table 1 Chemical Shift Ranges (ppm) Experienced at Room Temperature in Solution by Protons of Residues Bound to a Cobalt(II) or a Nickel(II) in the Active Site of Metalloproteins with Different Coordination Geometries

Coordination geometry	Ligand and proton type			
	Cys G- β	His <i>ortho</i> -like	His <i>meta</i> -like	Asp H- β , Glu H- γ
<i>Cobalt(II)</i>				
Tetrahedral	300–200	150–40	70–35	80–30
Penta-coordinate	300–200	130–30	80–50	
Octahedral			70–50	
<i>Nickel(II)</i>				
Tetrahedral	300–150		80–20	
Penta-coordinate	240–190		80–35	

Figure 1 ^1H NMR spectra of the thiocyanate adduct of cobalt(II)-substituted carbonic anhydrase recorded at different magnetic fields: (a) 90 MHz, (b) 200 MHz, (c) 600 MHz. The spectrum shown in (a) was recorded in D_2O in order to detect the broad A' signal otherwise covered by the A signal. 'Hatched' signals disappeared when the spectra were recorded in D_2O

give rise to cross peaks in COSY experiments even in the absence of scalar interaction between the protons. This mechanism is called relaxation allowed coherence transfer (RACT); it is absent in in-phase COSY or superCOSY experiments (see *Relaxation Processes: Cross Correlation and Interference Terms*).

4 COBALT(II)-SUBSTITUTED PROTEINS

The first spectrum of a cobalt(II)-substituted protein for which an attempt at sequence specific assignment was reported was that of cobalt(II)-substituted carbonic anhydrase (CA).¹³ CA is a zinc enzyme (see *Carbonic Anhydrase*) which catalyzes the hydration of carbon dioxide.¹⁴ The zinc ion is bound to three histidines with a roughly tetrahedral geometry. The fourth coordination position is accessible to the solvent or occupied by a water molecule. The latter molecule is transformed into a hydroxide group with a relatively low pK_a value. Substitution of the native zinc ion with cobalt(II) maintains about 50% of the enzymatic activity of the native protein. The cobalt(II)-substituted protein provides an NMR

spectrum which shows some well resolved, high-frequency-shifted signals. They are due to the histidine protons in *meta*-like positions with respect to the cobalt. Some of these signals have been readily assigned to the NH protons of the histidine rings due to their exchange with the bulk solvent.

As can be seen from the spectrum of the native cobalt(II)-substituted protein, reported at the bottom of Figure 2, the ^1H NMR signals due to the protons of the cobalt ligands are relatively broad (ca. 300 Hz at 200 MHz) and shifted within a relatively narrow shift range (+53 to +63 ppm). In addition, very few signals of protons not belonging to metal ligands are resolved outside the diamagnetic envelope. This is due to the tetrahedral geometry of the cobalt ion in the native form of this enzyme, which is characterized by small magnetic anisotropy and relatively long electron relaxation times. Hence the pseudocontact contribution to the shift is small and only protons belonging to the metal ion ligands experience sizable hyperfine shifts. This means that information remains substantially limited to the coordinated residues.

When inhibitors bind cobalt(II) without displacing the coordinated solvent molecule, a five-coordinate adduct is obtained in which cobalt(II) experiences a much larger magnetic anisotropy and shorter electron relaxation times. This means that several protons belonging to residues close to the cobalt ion, but not directly coordinated to it, are shifted substantially and well resolved outside the diamagnetic envelope. Furthermore the lines are sharper (ca. 200 Hz at 200 MHz) than in the spectrum of the native form. ^1H NMR spectra of adducts with several inhibitors are reported in Figure 2. On these spectra, classical NMR techniques for spectral assignment such as NOE (see *Nuclear Overhauser Effect*) and 2D NMR experiments (*COSY Two-Dimensional Experiments; Multidimensional Spectroscopy: Concepts; NOESY*) have been performed. They have led, for the adducts with nitrate, perchlorate and thiocyanate, to the assignment of the signals of the metal ligands and of several residues present around the active site.^{13,16} Some of these assignments have been confirmed by analysis of the spectra of samples produced with selectively deuterated amino acids.¹⁶

The assignment of several protons experiencing only pseudocontact shifts has allowed the calculation, using a best-fitting procedure and the knowledge of the X-ray structure of the protein, of the anisotropy and the orientation of the magnetic susceptibility (χ) tensor. The latter information is relevant for the knowledge of the electronic structure of the cobalt ion in the adduct. Furthermore, it allows the calculation of the shifts for all the protons sensing some coupling with the metal ion, which can help in further assigning other signals.^{13,16}

Extensive studies have also been performed on cobalt(II)-substituted carboxypeptidase (CPA) which is a zinc enzyme¹⁷ where the five-coordinate metal ion is bound to two histidines, a water molecule, and a bidentate glutamate. Cobalt substitution increases the enzymatic activity of native CPA. The protein is soluble only at high ionic strengths, i.e. in viscous solutions. This provides long τ_r values and consequently large line broadening due to Curie spin relaxation. Indeed, no high-field NMR experiments have been performed on this system.

Despite these problems, cobalt(II)-substitution in CPA has provided useful information on the local structural features at the metal ion and on the enzyme reactivity. The ^1H NMR

Figure 2 ^1H NMR spectra at 200 MHz of native and some anion adducts of cobalt-substituted carbonic anhydrase. 'Hatched' signals disappeared when the spectra were recorded in D_2O . (Reproduced by permission of Kluwer Academic Publishers from L. Banci, I. Bertini, C. Luchinat, and J. M. Moratal, in *Enzymatic and Model Carboxylation and Reduction Reactions for Carbon Dioxide Utilization*, eds. M. Aresta and J. V. Schloss, 1990, pp. 181–197)

spectrum of CoCPA (optimal field 90–200 MHz) shows three relatively sharp signals which have been assigned, through 1D NOE measurements, to *meta*-like protons of the two histidines. Two broader peaks have also been observed in the ^1H NMR spectrum of CoCPA and assigned, on the basis of their T_1 and T_2 values, to the two H- γ protons of the Co^{2+} -bound glutamate.

Information on the biochemistry of the enzyme was obtained by monitoring the changes in the ^1H NMR spectrum upon addition of inhibitors and substrate analogs.¹⁸ For instance, it has been observed that some inhibitors such as carboxylic acids bind the enzyme in a 2:1 ratio. The first inhibitor molecule binds through its carboxylate group to an Arg residue (Arg-145) present in the catalytic cavity. The binding of this molecule in the cavity breaks the strong H-bond present between the zinc-bound water molecule and a Glu residue (Glu-270) present in the cavity, and makes the water molecule easily displaceable by a second molecule of inhibitor which binds the metal ion directly.

Cobalt substitution has been successfully performed on Cu_2Zn_2 superoxide dismutase (SOD hereafter).¹⁹ This enzyme contains two metal centers connected by a histidine bridge. Cobalt(II) can substitute zinc in its native site. Several systems, with no metal or with diamagnetic metal ions [Ag(I) or Cu(I)] in the copper site, have been investigated with the aim of characterizing the zinc ion-binding site. In such systems, cobalt(II) is coordinated by three histidines and a unidentate aspartate. The spectra of such derivatives are all similar to each other. Eight signals are hyperfine-shifted in the high-frequency region, i.e. the three *meta*-like exchangeable HN- ϵ 2, the three nonexchangeable H- δ 2 protons of the imidazole rings and the signals of the two H- β protons of the bound aspartate. The observation of three HN signals in the case of $\text{Cu}_2\text{Co}_2\text{SOD}$ provided the first direct evidence that the imidazole bridge between the two metal ions is broken when the copper ion is reduced.²⁰ Indeed, this finding is particularly remarkable in the light of recent X-ray studies on the reduced form of the native ($\text{Cu}_2\text{Zn}_2\text{SOD}$) protein which show, in the solid state, no bridge-breaking in this form of the enzyme. The spectrum of $\text{Cu}_2\text{Co}_2\text{SOD}$ has been investigated through 1D NOE and 2D NMR experiments at different magnetic fields²⁰ in order to: (i) assign the far-hyperfine-shifted signals (1D NOE at 200 MHz), (ii) assign the signals of residues belonging to the active site but not bound to the Co^{2+} ion (2D NOESY, 600 MHz), and (iii) use the pseudocontact shifts [available because of the assignment at point (ii)] to obtain information on the χ tensor anisotropy and directions of the Co^{2+} ion in the zinc site, analogous to the case of cobalt(II)-substituted CA.

An interesting example of the utility of metal substitution in proteins with large molecular weight (MW) is provided by cobalt substitution of the native zinc ion in liver alcohol dehydrogenase (LADH), a dimeric protein of MW ca. 80 000. The metal ligands are two cysteines, one histidine, and a water molecule. Even in the case of this large molecule, the signals of the two Cys H- β protons and of the three histidine protons (including the *ortho*-like proton) have been observed. Of course, the higher the molecular weight, the larger is the Curie spin relaxation term. Hence, such signals are best detected at 60 MHz!²¹

Another example of a large protein for which cobalt substitution turned out to be useful with respect to obtaining information on the metal site is alkaline phosphatase (AP). AP is a large dimeric protein (MW 94 000) consisting of two identical subunits. Each contains three metal binding sites; in the native form two of these sites bind zinc while the third is specific for magnesium. Zinc has been substituted by cobalt(II) in its binding sites. Information on the metal ion ligands as well as on the metal uptake pathways has been obtained even on this large molecule.²²

One of the most recent applications of cobalt(II) substitution has been performed on zinc finger peptide CP-1.²³ At variance with the previously reported cases, zinc finger proteins have already been studied extensively through high-resolution ¹H NMR in their native form due to their relatively low molecular weight (see *Zinc Fingers*). However, cobalt(II) substitution has provided useful insights. Knowledge of the pseudocontact shifts of several resonances in the cobalt(II)-substituted protein has led the authors to calculate the χ tensor of the system. For a correct determination of the pseudocontact shifts, it is important to know the diamagnetic contributions to the shifts. The latter have been obtained by taking advantage of the assignment of the signals of the native protein.

Zinc proteins are not the only systems in which cobalt(II) substitution was successfully attempted. Iron has been substituted by cobalt(II) in several systems (see *Iron—Sulfur Proteins, Nonheme Iron Proteins, Transferrins*). Indeed, in the absence of magnetic coupling with fast relaxing metal ions and in nonheme proteins, both high spin iron(III) and high spin iron(II) give rise to relatively broad ¹H NMR signals.⁹ For this reason, although the ¹H NMR spectra of the iron(III)-containing protein Isopenicillin Synthase (INPS) have been recorded and several hyperfine-shifted signals observed, cobalt(II)-substituted INPS has been prepared in order to obtain hyperfine-shifted signals sharp enough to perform 1D NOE experiments. These have led to the tentative proposal of the structure of the active site (no X-ray data are available) and of a catalytic mechanism.²⁴ Similar considerations hold also for the signal linewidths in rubredoxin (Rd) (see *Iron—Sulfur Proteins*) where the iron ion has a tetrahedral geometry and is coordinated to the sulfur atoms of the four cysteines. In this system, cobalt(II) and nickel(II) substitution was also performed. The ¹H NMR spectra are characterized by sharp and well-resolved signals, although no firm assignment is available for the spectra.²⁵

Metallothioneins (MT) constitute a class of small proteins containing clusters of the type Cd₄S₁₁ and Cd₃S₉. Titration of the apoprotein with cobalt(II) has been followed using NMR and has allowed the authors to study the uptake pathway of the metal ions. The Co₃S₉ cluster was first formed. The protein containing this cluster shows broad hyperfine signals, probably because the Co₃S₉ cluster experiences some fluxionality that broadens the lines beyond detection.²⁶ The ¹H NMR spectrum of the fully-substituted protein (Co₇MT) shows a large number of sharp, very high-frequency-shifted signals arising from the H- β protons of the cobalt(II)-coordinated cysteines. Such signals are shifted by up to +400 ppm. Detection of ¹H NMR signals at 600 MHz over such a large spectral width required the use of a fast ADC (9-bit digitizer over 10 MHz) (see *Spectrometers: A General Overview*). An extensive pairwise assignment of the H- β cysteine protons was performed by 1D NOE and 2D NOESY experiments as well as by observing the temperature dependence of the shifts, interpreted on the basis of a magnetic coupling scheme among the metal ions.²⁶

Substitution of the native iron(III) ion in transferrins (TRN, MW 90 000) (see *Transferrins*) with cobalt(II) provided derivatives which showed, at 90 MHz, several high-frequency-shifted signals despite the large molecular weight of the protein.²⁷ The protein contains two metal binding sites which are not equivalent as revealed by ¹H NMR spectra. The observed signals were attributed to the presence of histidine and tyrosine residues as ligands to the metal ions. This example

shows that the presence of a suitable metal ion can aid the characterization through NMR of even large proteins.

The blue copper protein azurin (Az) (see *Copper Proteins*) has been investigated through ¹H NMR of the cobalt(II)- and nickel(II)-substituted derivatives.²⁸ The metal ion is penta-coordinate, its ligands being two histidines, one cysteine, one methionine, and the oxygen of the carbonyl group of a glycine residue. This protein has a relatively small molecular weight (16 000) which makes the Curie spin relaxation less efficient than in the systems previously described. The signals of the protons of the metal ion ligands are therefore relatively sharp. The H- β proton signals of the coordinated cysteine are shifted by more than +200 ppm while the signals of the ring protons of the two histidines fall in the usual 60–30 ppm region. The signals of two geminal proton pairs, which were tentatively assigned to the H- α protons of the metal-coordinated glycine and to the H- γ protons of the coordinated methionine, are observed with one signal shifted at low frequency and its geminal partner at high frequency for both pairs.²⁹ This behavior has not yet been rationalized, but it could be due to the different M–S(O)–C–H dihedral angles experienced by the two protons in each pair. This would make the spin density different on each of the two protons.

Experiments involving nuclei other than protons are much less common, even if quite promising. Heteronuclear multiple quantum coherence (HMQC) experiments (see *Heteronuclear Shift Correlation Spectroscopy*) on ¹⁵N-enriched samples have been performed on cobalt(II)-substituted CA,⁶ and several scalar ¹⁵N–¹H couplings between residues close to the cobalt ion have been detected.

5 NICKEL(II)-SUBSTITUTED PROTEINS

There are several examples in which nickel substitution has been performed on the same proteins where the native metal ion has also been replaced by cobalt. As previously discussed, nickel(II) is, in principle, more suitable for the investigation of tetrahedral centers and less useful in the case of hexa-coordinate chromophores. Indeed, the nickel(II) ion in NiCPA in the presence of two moieties of D-phenylalanine induces broad lines and small pseudocontact shifts due to the small magnetic anisotropy.³⁰ In contrast, the ¹H NMR spectrum of NiCPA without any inhibitor shows sharp lines for the *meta*-like protons of the bound histidines,³⁰ the opposite of that observed for cobalt(II)-substituted CPA.

Nickel(II)-substituted CA has also been investigated through ¹H NMR, although the interest in such derivatives from the biochemical point of view is limited due to the severe reduction of activity. For those adducts of NiCA for which NMR studies have been performed, information similar to that obtained upon cobalt(II) substitution was achieved.³¹

In the case of tetrahedral chromophores such as Fe^{III}Rd and Cu^{II}Az, nickel(II) substitution produces derivatives with narrower lines relative to the corresponding cobalt(II) substituted derivatives.³² In the case of zinc fingers, also, nickel(II) substitution produces narrower hyperfine-shifted ¹H NMR signals with respect to those observed in the cobalt(II) derivative. However, no assignment of the hyperfine-shifted signals has been attempted for the nickel derivative.³³

Finally, a derivative with a nickel(II) in the zinc site of SOD and no metal in the copper site has been prepared and

characterized through NMR,²⁰ again obtaining information similar to that on the analogous cobalt(II) derivative.

6 COBALT(II)- AND NICKEL(II)-SUBSTITUTION IN MAGNETICALLY COUPLED DIMERS

Cobalt(II) and nickel(II) are not only efficient probes for NMR investigation in themselves, but they can also drastically reduce the electron relaxation rates of a slow-relaxing metal ion through magnetic coupling.⁹ This coupling allows the slow-relaxing ion to relax through the efficient mechanisms of the fast-relaxing metal ion. The effect depends on the extent of the magnetic coupling constant; in the limit of $J/\hbar \gg \tau_s^{-1}$ (where τ_s is referred to the fast-relaxing metal ion) the relaxation rate of the slow-relaxing metal ion approaches that of the fast-relaxing ion^{9,34} (see *Paramagnetic Relaxation in*

Solution, Relaxation Theory: Density Matrix Formulation). Under such conditions, even the signals of nuclei coupled to a slow-relaxing metal ion which, when isolated, would induce a dramatic increase in the linewidth, can be easily detected because they are sharp enough for the application of standard high-resolution NMR techniques.

An elegant application of the above considerations is provided by the replacement of native zinc ion in $\text{Cu}^{\text{II}}_2\text{Zn}_2\text{SOD}$ by cobalt(II) and nickel(II). The copper(II) ion is characterized by τ_s values of the order of 10^{-9} s which produce a dipolar contribution to the linewidth of a proton at 5 Å from copper (as for the *meta*-like protons of the coordinated histidines) of 2000 Hz. However, the magnetic coupling of copper with cobalt(II) or nickel(II), which relax much faster than copper(II), produces a drastic reduction of the relaxation times of the latter metal ion. The ^1H NMR spectra of $\text{Cu}_2\text{Co}_2\text{SOD}$ and of $\text{Cu}_2\text{Ni}_2\text{SOD}$ are reported as the upper traces in Figure 3.²⁰

Figure 3 600 MHz NOESY spectra of $\text{Cu}_2\text{Co}_2\text{SOD}$ (a) and $\text{Cu}_2\text{Ni}_2\text{SOD}$ (b) in the region of hyperfine, high-frequency-shifted signals. The 1D spectra are also reported on the top of the NOESY maps. Signals marked by asterisks arise from protons of residues bound to the cobalt(II) or nickel(II) ions. Signal and cross peak labeling refer to the assignments summarized by Bertini et al.²⁰ Experimental conditions were: (a), lower map mixing time 4 ms, relaxation delay 80 ms, 256 experiments in F_1 and 512 experiment in F_2 ; upper map mixing time 15 ms, relaxation delay 150 ms (in order to better detect connectivities between hyperfine shifted signals and diamagnetic signals); (b), mixing time 15 ms, relaxation delay 80 ms, 512 experiments in F_1 and 1024 experiments in F_2 . The inset in (b) shows a region of a NOESY spectrum recorded under the same experimental conditions at 300 MHz. All the observed connectivities in $\text{Cu}_2\text{Co}_2\text{SOD}$ involve signals of copper-coordinated residues. In the NOESY map of $\text{Cu}_2\text{Ni}_2\text{SOD}$, connectivities 1–5 arise from intraresidue connectivities involving imidazole protons of residues bound either to Ni(II) (1) or Cu(II) (2–5). Connectivities 6 and 7 arise from interresidue contacts involving copper-coordinated histidines

It should be noted that the signals of the protons of the copper ligands are even sharper [due to the lower S value of copper(II) than of cobalt(II) and nickel(II)] than those of the cobalt or nickel ligands. All the metal–ligand proton signals, as well as several signals due to protons of residues located close to the two paramagnetic centers, have been firmly assigned through 1D NOE (see *Nuclear Overhauser Effect*) and/or 2D NOESY (see *NOESY* experiments). In Figure 3 the NOESY spectra of $\text{Cu}_2\text{Co}_2\text{SOD}$ and $\text{Cu}_2\text{Ni}_2\text{SOD}$ are reported.^{20,35,36} In these maps, besides many intraresidue connectivities, some inter-residue connectivities are also detected between the copper ligand protons. In $\text{Cu}_2\text{Ni}_2\text{SOD}$ some intraresidue connectivities have also been detected for nickel(II) ligand protons (see inset in Figure 3), while no connectivities between protons of residues coordinated to the cobalt(II) ion in $\text{Cu}_2\text{Co}_2\text{SOD}$ could be observed. The latter effect is due to the very short T_2 values of the signals which render the broad NOESY cross peaks expected in these cases difficult to detect.

The signals of the protons in the copper site are sharper in $\text{Cu}_2\text{Ni}_2\text{SOD}$ than in $\text{Cu}_2\text{Co}_2\text{SOD}$. This is the result of the shorter electron relaxation times of nickel(II) than of cobalt(II) in tetrahedral geometry. For the signals of the ligands of the zinc site, the spin state of Ni^{2+} , $S = 1$, makes the Curie contribution to their linewidth smaller than for those in the cobalt(II)-substituted derivative.

Cobalt(II) has also been used to replace the native copper(II) to obtain either $\text{Co}_2\text{Zn}_2\text{SOD}$ or $\text{Co}_2\text{Co}_2\text{SOD}$; the above derivatives have been investigated through NMR and the signals of the metal-coordinated residues have been observed even if no detailed assignment was attempted.²⁰

The ^1H NMR signals for metal–ligand protons have also been detected in $\text{Co}_2\text{Cu}_2\text{AP}$, for the ligands of copper ion,²² and in iron(II)–cobalt(II) uteroferrin³⁷ (see *Nonheme Iron Proteins*) for the ligands of the iron(II) ion. Indeed, the effect of the coupling is quite general. In all the proteins which contain two metal binding sites close enough that magnetic coupling can occur, NMR characterization of the metal sites can be successfully performed provided that one of the metal ions has short electron relaxation times.

Heteronuclear NMR spectroscopy has been rarely applied in the case of dimers. ^{15}N – ^1H HMQC spectra (see *Heteronuclear Shift Correlation Spectroscopy*) have been recorded on $\text{Cu}_2\text{Co}_2\text{SOD}$, detecting the ^{15}N – ^1H scalar couplings for the copper-bound histidines.³⁸ This is the first case in which ^{15}N – ^1H connectivities involving residues directly coordinated to the metal center of a paramagnetic protein have been observed.

7 CONCLUSIONS

Some of the examples discussed above clearly indicate that cobalt(II) substitution is *still* a powerful technique for the ^1H NMR spectroscopy of metalloproteins, although the actual capabilities of ‘standard’ multidimensional experiments are such that the 3D structure of proteins up to MW 30 000 can now be determined (see *Biological Macromolecules: Structure Determination in Solution, Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*). In the case of proteins containing paramagnetic metal ions, which provide hyperfine-shifted signals which are

too broad, Co^{2+} and/or Ni^{2+} substitutions allow a good structural characterization of the protein region around the metal center. In the case of relatively small proteins, standard NMR experimental procedures for diamagnetic systems can be successfully combined with the analysis of 2D NOESY and COSY maps designed for the detection of connectivities between the hyperfine shifted signals to obtain the overall 3D protein structure in solution. Hence, the ‘paramagnetism’ of the system is no longer a drawback for the complete characterization and for the determination of the solution structure. In the case of large proteins such results cannot be achieved, but valuable local information on the active site can be obtained. Finally, we would like to stress the relevance of the evaluation of the χ tensor anisotropy and directions in cobalt(II)-substituted systems. Analysis of pseudocontact shifts, as formerly performed in the case of heme proteins, has also provided satisfactory results in cobalt(II)-substituted systems. More frequent utilization of such an approach is expected in the future.

1 INTRODUCTION

The presence of a 3d transition metal in their interior makes Cu proteins challenging and interesting subjects of study by NMR techniques. In addition, in a number of cases the properties of the protein matrix make them eminently suitable for the application of advanced NMR spectroscopic techniques, despite the occasional inconvenience caused by the presence of a redox-active metal.

Although copper itself is NMR-visible this property has hardly been used in the study of copper proteins.¹ The two naturally occurring stable copper isotopes (⁶³Cu and ⁶⁵Cu, natural abundances 69.2% and 30.8%) have nonzero spin ($I = \frac{3}{2}$ for both isotopes), but the accompanying nuclear quadrupole moment is large enough to cause considerable relaxation and line broadening, except for cases where the metal environment is highly symmetric and the electrical field gradient is consequently zero. For coordination compounds the latter may sometimes be the case, but protein environments are usually of low symmetry and Cu NMR spectroscopy, therefore, has been of little practical value in the study of Cu proteins.

Copper in proteins may occur in more than one redox state: Cu(I) or Cu(II). Copper(I) is diamagnetic and produces no problems in the measurement and interpretation of NMR spectra. However, the metal is easily oxidized and changes over to the (paramagnetic) Cu(II) state, which may cause complications from a spectroscopic point of view. The electronic spin–lattice relaxation of Cu(II) is too slow (relaxation times of 1–3 ns) for Cu to be useful as a shift reagent. Instead, resonances from nuclei close to the metal are broadened beyond detection. This is often a nuisance, but it can be used to advantage in kinetic experiments where the rate of electron transfer to and from the Cu is measured (vide infra). The broadening effect may also be used as an additional help in the assignment of some peaks in the NMR spectrum of the protein. The metal then serves as a relaxation probe.

Thus the presence of Cu may impart some experimental obstacles to high-resolution studies of Cu proteins. NMR spectroscopists have tried to circumvent these by replacing the Cu with paramagnetic shift probes such as Ni(II) and

Co(II), which have shorter electron spin relaxation times, or with diamagnetic redox-inactive metals such as Ag(I), Zn(II), Cd(II), and Hg(II).^{2–5} Some of the latter nuclei are directly accessible to NMR spectroscopy (¹⁰⁹Ag, ¹¹³Cd, ¹⁹⁹Hg).

Copper proteins have been distinguished on the basis of the structural and spectroscopic characteristics of their metal sites.^{6,7} Type-I sites contain a single copper ion covalently anchored to the protein by three metal–ligand bonds, two of them provided by histidines that act as N-donors, and one by a cysteine that coordinates to the Cu via its S- γ atom. The Cu is located almost in the plane of the three ligands. A fourth ligand, usually a methionine, sometimes a glutamine, occupies one of the axial positions, while in the azurins an additional main-chain carbonyl oxygen may coordinate weakly at the opposite axial position. Type-I sites invariably function in electron transfer.

Type-II sites also contain a single Cu atom, often coordinated in a square planar configuration by four nitrogen/oxygen donors and one or two axial ligands, one of which may be a water molecule or the substrate. They are found, for instance, in various oxidases, often in conjunction with an organic cofactor.

Type-III sites contain a Cu₂ dimer which is fixed within the protein framework by six histidines. They function in the transport of oxygen (hemocyanins) or the activation of oxygen in oxidase or oxygenase reactions (tyrosinase).

For a long time the copper sites in the blue oxidases like ascorbate oxidase and laccase were thought to be of a composite of type-I, -II, and -III sites. Crystal structure determination of ascorbate oxidase has made it clear that at least in this oxidase the Cu atoms occur in the form of a single type-I site plus a trimer of Cu atoms arranged in an equilateral triangle, which may be considered as a new type of site (type-IV).

Finally, recent work on cytochrome *a*,*a*₃ oxidase and nitrous oxide reductase has provided evidence for the occurrence of a new type of Cu₂ dimer in which the Cu atoms are possibly bridged by a cysteine.^{8,9}

Until very recently the size of most copper proteins precluded the study of their structure by means of high-resolution ¹H NMR techniques. Investigations were thus limited to studies of the metal site and its immediate surroundings, as in the case of proteins containing a type-I or a type-II Cu center. Only in the case of the so-called blue (type-I) copper proteins did the size of the proteins appear sufficiently small to allow extensive structural and mechanistic studies by high-resolution 2D and 3D NMR techniques. No elaborate NMR studies of proteins with type-III or type-IV sites seem to have been reported to date. Very recently the application of *rec*-DNA techniques has allowed the isolation of single domains of larger Cu-containing proteins, and the study of these domains by NMR techniques is presently being pursued by various groups.

In the following sections the progress achieved over the past two decades in the NMR study of Cu proteins is briefly reviewed.

2 BLUE COPPER PROTEINS

2.1 Introduction

The so-called small blue copper proteins (96–155 residues), which invariably contain a type-I Cu site, were described

for the first time at the end of the 1950s/beginning of the 1960s (for recent reviews see References 10 and 11).^{10,11} The following subclasses are distinguished at present: proteins involved in bacterial respiratory electron transport (azurin, pseudoazurin, amicyanin, rusticyanin, and auracyanin), photosynthetic plant and algal proteins (plastocyanin), and plant proteins with unknown function [either nonglycosylated: 'cucumber basic blue protein' (CBP) and plantacyanin; or glycosylated: stellacyanin, umecyanin, mavicyanin, and cucumber peeling cupredoxin (CPC)]. During the course of time it gradually transpired that their relatively small size (10–15 kDa), robustness under extremes of pH and temperature, ease of isolation and purification, and stability in solution at high concentrations made the blue copper proteins excellently suitable for detailed NMR investigations. Their attractiveness was further enhanced when the crystal structures of a number of them were solved at the end of the 1970s/beginning of the 1980s (plastocyanin,¹² azurin¹³). Later the structures of amicyanins (Amcs),^{14,15} CBP,¹⁶ and pseudoazurin were reported.^{17,18}

The presence inside the protein of a metal capable of occurring in two oxidation states, one of which is paramagnetic, further heightened the appetite of NMR spectroscopists towards applying the tricks of their trade in unraveling the effect of the metal on the appearance of the NMR spectra. Most of the NMR studies have been performed on the azurins (Azus) from *Pseudomonas aeruginosa* and *Alcaligenes denitrificans*,^{19,20} the plastocyanins (Pcs) from *Phaseolus vulgaris* (French bean),²¹ spinach and *Scenedesmus obliquus*,^{22,23} amicyanin (Amc) from *Thiobacillus versutus*,²⁴ and stellacyanin from *Rhus vernicifera*,²⁵ but brief reports have also been published of various other blue copper proteins.^{26–30} Finally, it has recently been shown that the small blue copper proteins yield fairly easily to the application of *rec*-DNA and site-directed mutagenesis techniques and this has added a new dimension to their study.¹¹ For instance, the application of multidimensional heteronuclear MR techniques on isotopically-enriched (¹³C and ¹⁵N) proteins has now become available.

2.2 Copper Site Structure

Some of the first investigators to study copper proteins by NMR techniques were Blumberg et al.,³¹ who around 1965 tried to assess the accessibility of the metal towards water molecules. They measured the relaxation enhancement of the bulk water protons as a function of the protein concentration and the oxidation state of the metal(s). In Pc, for instance, the Cu appeared inaccessible towards water. Application of this technique only required the study of the easily observable bulk water signal and not that of the protein. It would take 10 more years before spectrometers of sufficient resolution and sensitivity would become available to enable the successful tackling of the latter task. In the second half of the 1970s the first reports on the ¹H NMR spectra of various Pcs,^{32–35} of *P. aeruginosa* Azu,^{36–38} and of *R. vernicifera* stellacyanin appeared.³⁹ Also natural abundance ¹³C NMR studies of Azu and Pc were reported around this time.^{40,41} The spectra were much too complex to allow a detailed assignment of the signals, and attention primarily focused on the assignment by type of a few amino acids such as histidines and methionines, which give rise to easily identifiable singlet signals and (in the case of histidine) a characteristic pH titration behavior.

Since the four canonical ligands of a type-I Cu site comprise (apart from a cysteine) two histidines and a methionine, the structure of the Cu site in blue copper proteins rapidly became a popular subject of study by NMR techniques. By comparing the spectra of the Cu(II), Cu(I), apo-, and Hg(II)-substituted forms,³⁷ the ligands of the Cu could be identified correctly in Azu and Pc. Later on, these assignments were elaborated by 1D and 2D ¹H NMR and 2D ¹H{¹¹³Cd} and ¹H{¹³C} NMR studies.^{42–48} The ¹H NMR signals of the metal ligands could be shifted outside the envelope of the regular NMR spectrum by replacing the Cu by paramagnetic shift probes such as the 3d metal ions Co(II) and Ni(II).^{48,49} This essentially provided clearly resolved signals from protons in the first coordination shell of the metal, but the unraveling of the various contact and pseudocontact contributions to the paramagnetic shifts proved too complicated to make this subterfuge much use in the analysis of the behavior and structure of the Cu site.

An illustration of the difficulties of this approach is provided by the study of Dahlin et al.²⁵ who made an elaborate attempt to identify the Cu ligands in the plant blue copper protein stellacyanin. The nature and coordinating properties of the fourth Cu ligand in this protein had long been an enigma, since the lack of methionines in the amino acid sequence provided indelible proof that the metal-binding site in stellacyanin was at least different in one respect from that in the Azus and Pcs. Despite careful analysis, the NMR results obtained on the Co(II)-substituted form of stellacyanin remained ambiguous. Subsequently, structural research on the related 'cucumber blue protein',⁵⁰ and site-directed mutagenesis studies on Azus,⁵¹ have made it clear that the fourth ligand in stellacyanin is probably a glutamine.

The study of Ni(II) and Co(II)-substituted Azus has recently been taken up again by Moratal et al.^{52,53} who are applying multidimensional NMR techniques to study paramagnetically shifted signals. This work may provide further insight into the malleability of the metal site, as probed already by NMR and XRD (X-ray diffraction) studies of wild-type and mutant blue copper proteins in their apo and holo forms, or with Cd(II), Hg(II), or Zn(II) substituted at the metal site.^{10,11} The latter investigations have demonstrated that the metal site is preformed by the protein matrix, but does still retain some flexibility and is able to adapt somewhat to the metal that is substituted for the Cu.

Several attempts have been made to identify differences in structure and the Cu-binding mode of the metal sites between the Azus and the Pcs. Additional inspiration for this work came from XRD reports showing that the Cu site in Pc more closely resembled a distorted tetrahedron, while the coordination of the Cu in Azu was more like that of a trigonal bipyramid, with three strong almost in-plane ligands (two histidines and a cysteine) and two axial ligands, provided by a methionine sulfur (Met-121) and a backbone carbonyl oxygen (Gly-45).^{6,11} Differences in chemical shift of the ¹¹³Cd NMR signal of Cd-substituted Azu and Pc seemed diagnostic of a difference in electronic structure,^{54,55} but the difference was not easy to interpret. Further, the early ¹³C NMR studies of Azu implicated close proximity or possibly binding of a backbone carbonyl oxygen to the Cu.⁴⁰ Debate is still continuing regarding the amount of covalency involved in the Cu–S(Met) bond and the actual involvement of the Gly-45 carbonyl in determining the Cu-site properties in the Azus.

2.3 The Effects of pH

A clear difference between Pcs and Azus was provided by the pH titration behavior of the metal site. While the Cu site in the Azus is insensitive to pH, the geometry of the Cu site in the reduced form of the Pcs changes from fourfold to threefold towards low pH as one of the histidine ligands (His-87, *P. nigra* numbering) becomes protonated and dissociates from the Cu. This was beautifully documented by a series of XRD studies by Freeman et al.,⁵⁶ and confirmed later by ¹H NMR studies.^{42,57,58} A similar effect is seen to occur in the Amcs described for the first time in the early 1980s, i.e. the blue copper proteins that act as electron acceptors of methylamine dehydrogenases in C₁ organisms. Thus the Amc from *T. versutus* was studied in detail by NMR spectroscopy, and the dissociation of the histidine ligand at low pH (His-96, *T. versutus* numbering) was shown to occur in two steps with different timescales.⁵⁹ As the change in coordination with pH is seen only for the reduced and not for the oxidized form of the protein, electron transfer at low pH is accompanied by a large change in conformation around the Cu. It is not surprising, therefore, that a slowing down of the electron transfer as catalyzed by Amc or Pc is observed under acidic conditions.⁵⁹ A similar lability of the Cu site probably occurs in the pseudoazurins.⁶⁰ It appears, therefore, as what was initially considered an anomaly in the case of Pc (a pH-dependent Cu-site structure) relative to Azus, seems to be the rule for small blue copper proteins and that the pH-insensitive Cu site of the Azus constitutes the anomaly.

A pH effect of a different kind was observed for Azu from *P. aeruginosa*, and for a long time its precise nature and mechanistic relevance remained a source of speculation. Almost from the very beginning of the NMR studies on the Azus it appeared that Azu from *P. aeruginosa* is involved in a pH-dependent equilibrium between two conformations which on the NMR timescale are in slow exchange.^{37,46} From successive NMR studies it transpired that residue His-35 is responsible for this phenomenon and that the two conformations of the protein are related to the different states of protonation of His-35. Subsequent studies of the kinetics of the electron exchange between Azu and cytochrome C₅₅₁ seemed to necessitate the assumption that Azu may occur in two states, one redox-active and the other one redox-inactive, and that the equilibrium between them was pH-dependent. The pK_a of this transition appeared to be the same as that of His-35. Since in the crystal structure His-35 is in van der Waals contact with the Cu ligand His-46, the hypothesis was advanced that (one of) the electron transfer pathway(s) in Azu runs through His-35 and His-46, and that His-35 might act as a switch depending on the pH of the surrounding medium. This hypothesis was subsequently tested by a large number of groups.⁶¹

Eventually, a combination of (a) NMR studies of the electron self-exchange (ESE) reaction of wild-type Azu and of Azus with mutations at residue 35 and in the hydrophobic patch surrounding the other histidine ligand (His-117),^{62,63} (b) kinetic studies of the electron exchange between Azu mutants and physiological partners such as cytochrome C₅₅₁ and nitrite reductase,⁶⁴ and (c) XRD studies of wild-type and mutant Azus^{65,66} have led to the conclusion that His-35 is not in the electron transfer path to and from the Cu. Instead, Cu-ligand His-117, which pierces the protein surface at the position of

the hydrophobic patch, provides the sole port of exit and entry for the electrons. Small changes in the chemical shifts of the protons in the first and second coordination shell of the metal as a function of protonation state of His-35 reflect a 180° flip in the Pro-36/Gly-37 peptide bond which is at H-bonding distance of the N-δ of His-35. The position of His-35 relative to the Cu site is hardly affected. Finally, the redox activity of the protein appears to be independent of pH.

The only parameter relevant to the redox properties of the Azu affected by the change in protonation of His-35 is the midpoint potential which drops by 60 mV if His-35 is deprotonated.⁶³ It is interesting to note that in Pc a pathway running through Cu ligand His-87 (*P. nigra* numbering) similar to the His-117 pathway in the Azus has been delineated, but that here a second, albeit less efficient route for electron transfer has been identified starting at the 'eastern side' of the protein at the Tyr-83 residue.^{10,67,68}

2.4 Electron Transfer

The ESE rates of the blue copper proteins have attracted considerable attention apart from the metal site. It turned out that NMR methods are particularly suitable for the determination of these rates.^{3,69,70} Due to small conformational differences the NMR spectra of the oxidized and reduced forms of a blue copper protein show numerous small differences. In addition, in the paramagnetic [Cu(II)] species, the signals from nuclei close to the Cu are broadened beyond detection. In a solution containing a mixture of the reduced and oxidized form, exchange of an electron may occur when an oxidized and a reduced molecule collide. As a result two observations can be made. First, as the exchange becomes faster, signals from the same proton which occur at different positions in the spectra of the oxidized and reduced protein begin to merge. Secondly, signals that are only observed for the diamagnetic species may begin to broaden.

The first phenomenon may be adequately analyzed with customary 'chemical exchange' theory and information about the ESE rate can be obtained directly. The second phenomenon can be analyzed most readily in the so-called strong pulse or slow exchange limit. This limit applies if during the time the protein is in the paramagnetic state the nuclear spins are dephased to a sufficient extent that any phase coherence left over from the period the protein was diamagnetic is wiped out. Thus, effectively only the (lifetime broadened) signal deriving from the diamagnetic protein is observed and the broadening in (rad s⁻¹) is directly equal to the inverse lifetime of the diamagnetic state. For the paramagnetic dephasing to be strong enough, the nucleus whose signal is studied should be close enough to the copper. In practice, the strong pulse condition is met for nuclei which are located on side chains of the Cu ligands. When nuclei further away from the Cu are used for this technique erroneous results may be obtained, as is illustrated by a study of Azu where the ESE-induced broadening of the His-35 proton signals was used to determine an ESE rate which was two orders of magnitude off the correct value.^{71,72}

The high second order ESE rates ($8 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$) observed for the Azus have been interpreted as indicating that formation of the association complex is thermodynamically favorable.^{71,73,74} Current ideas are that the edges of the His-117 side chains in both Azus in the association complex

have to come sufficiently close for efficient electron transfer to occur, this being achieved when the two Azu molecules associate with their hydrophobic patches along each other. In the case of the Pcs a similar association complex has to be formed, but here the association is hampered by the presence of charged residues in or close to the hydrophobic ('northern') patch of the protein surface, which for most plant Pcs results in ESE rates of less than $1 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$.^{75,76} For the algal Pcs, which lack these charged residues in the hydrophobic patch, the ESE rates may reach values of $10^5 \text{ M}^{-1} \text{ s}^{-1}$.⁷⁰ For Amc, which in some respects resembles the algal Pcs, rates on the order of $1 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ have been measured.⁵⁹ In line with these observations is that the ESE rates of the Azus are independent of ionic strength,⁷³ while those of the Pcs,⁷⁵ and to a smaller extent those of the Amcs,⁵⁹ increase when salts are added to the sample solution. Multivalent cations such as Mg(II) have appeared especially effective in promoting ESE.⁷⁵ Interestingly, redox-active compounds, such as ferricyanide, may catalyze the protein ESE reaction.^{35,77}

To identify areas on the protein surface where other electron transfer proteins might possibly associate, the complexation of blue copper proteins with redox-inert paramagnetic transition metal compounds serving as charged analogs of protein partners have been studied.^{22,57,58,78–80} By identifying and assigning the affected signals in the NMR spectrum, the location of the complex on the protein surface could sometimes be identified. In a similar way the association of blue copper proteins with proteins such as cytochrome *c* and cytochrome *f* have been studied directly. For this, the perturbation of the NMR spectrum of the blue copper protein that resulted from the admixture of the cytochrome and vice versa was investigated.^{81–83} The inhibition of protein/protein complex formation by transition metal complexes was also studied in this manner. For this method to be successful it is of importance to dispose of a complete assignment of the NMR spectrum of the protein under study. Such assignments are now available for a number of cases.

2.5 Structural Studies

Complete NMR assignments for blue copper proteins started to become available in the second half of the 1980s. Two-dimensional ^1H NMR assignment studies have been performed on the Pcs from spinach,²² *P. vulgaris* (French bean),^{84,85} and the alga *S. obliquus*.⁸⁶ The assignment of the ^1H NMR spectrum of Amc from *T. versutus* has also been accomplished using 2D NMR techniques.²⁴ Finally from the analysis of 2D and 3D homo- and heteronuclear NMR experiments, complete ^1H and ^{15}N NMR assignments have become available for the Azus from *P. aeruginosa*¹⁹ and *A. denitrificans*.²⁰ An interesting observation for the latter two proteins was that the differences in C- α -H chemical shifts did not average out to zero, contrary to the differences in amide proton chemical shifts. This is the subject of further study at the moment.

The secondary structures derived from the NMR results compared well with the published XRD structures in the case of the Pcs and Azus. For the Amc no XRD results were available initially, and the NMR results (later confirmed by more elaborate NMR studies and XRD investigations) showed an unusual extension of the N-terminus compared with the Pcs and Azus. Subsequent determination of the 3D

structures of the Pcs from *S. obliquus*²³ and *P. vulgaris*²¹ on the basis of the NMR results showed extensive similarity with the XRD-derived 3D structure of Pc from *P. nigra*. The NMR results formed a nice starting point for further structural investigations. Wright and coworkers studied the denaturation and refolding of Pc as well as the folding behavior of peptide fragments that were synthesized according to the natural amino acid sequence of the Pc. In this way a beginning could be made with the tentative delineation of the natural folding pathway(s) of Pc.^{87,88} The 3D structure in solution of Amc from *T. versutus* was determined by NMR methods at the same time that an XRD study could be completed.^{14,89} A detailed comparison of the two structures still has to be performed, but the overall structures do show a great deal of similarity.

3 NONBLUE COPPER PROTEINS

3.1 Superoxide Dismutase (SOD)

SOD is a eukaryotic homodimeric metalloenzyme (M_r approx. 30 kDa) which catalyzes the disproportionation of O_2^- to O_2 and H_2O_2 .⁹⁰ Each monomer contains a structural Zn(II) site and a catalytic type-II Cu(II) site. An imidazolate bridges the two metal ions which are about 6 Å apart. The metal ions in the native enzyme $\text{Cu(II)}_2\text{Zn(II)}_2\text{SOD}$ can be readily removed or substituted. The crystal structures of bovine and spinach $\text{Cu(II)}_2\text{Zn(II)}_2\text{SOD}$ ^{91,92} and of the $\text{Cu(II)}_2\text{Co(II)}_2$ derivative of bovine SOD⁹³ have been determined by X-ray crystallography. NMR experiments have been performed with bovine, human, and yeast SODs, which have similar catalytic, spectroscopic, and structural properties.

Because of their relatively large size, the assignment of all resonances in the ^1H NMR spectrum has not been achieved to date for any SOD. NMR experiments have been directed mainly at the study of the metal sites and their environment, including the interaction with exogenously added molecules like small anions and water. In the 1970s, work on SOD commenced by looking at the C- δ H and C- ϵ H resonances of His residues. The resonances of His ligands of the metal ions were tentatively identified by their broadening in the ^1H NMR spectrum of paramagnetic $\text{Cu(II)}_2\text{Zn(II)}_2\text{SOD}$ when compared with the spectrum of diamagnetic $\text{Cu(I)}_2\text{Zn(II)}_2\text{SOD}$,^{94–96} and by the reduction of their C- α ,H exchange rate.⁹⁷ His resonances were also investigated in the spectra of the diamagnetic forms $\text{E}_2\text{E}_2\text{SOD}$ (E denotes an empty metal site), $\text{E}_2\text{Zn(II)}_2\text{SOD}$, and $\text{Zn(II)}_2\text{Zn(II)}_2\text{SOD}$. It appears that the metal-site conformation is preserved among these derivatives.

A breakthrough in the study of the metal sites of SOD was achieved when Bertini et al. investigated the metal derivative $\text{Cu(II)}_2\text{Co(II)}_2\text{SOD}$ by NMR spectroscopy.^{90,98} Because of the magnetic coupling between Cu(II) and Co(II), which reduces the electron relaxation time of Cu(II), the resonances of protons near the Cu(II) ion are much less broadened than for $\text{Cu(II)}_2\text{Zn(II)}_2\text{SOD}$, and moreover experience large isotropic hyperfine shifts like the resonances of protons near the Co(II) ion. Similar observations have been made for $\text{Cu(II)}_2\text{Ni(II)}_2\text{SOD}$.⁹⁹ The metal-site ^1H resonances have been assigned, firstly by studying the effects of $^1\text{H}/^2\text{H}$ exchange on the 1D ^1H NMR spectrum and by analyzing 1D T_1 , T_2 and ^1H NOE measurements,^{90,99} and

secondly by the recent application of 2D ^1H NMR techniques (COSY, NOESY).^{2,100–102} Using $\text{Cu(II)}_2\text{Co(II)}_2\text{SOD}$ and $\text{Cu(I)}_2\text{Co(II)}_2\text{SOD}$, it was shown that the breakage of the imidazolate bridge between the metal ions upon reduction of the copper occurs at the Cu side,¹⁰³ a result that had already been anticipated on the basis of ^{113}Cd NMR spectroscopy of $\text{Cu(II)}_2\text{Cd(II)}_2\text{SOD}$ and $\text{Cu(I)}_2\text{Cd(II)}_2\text{SOD}$.¹⁰⁴ From NMR experiments involving both protons and nuclei such as ^{13}C , ^{19}F , ^{31}P , and ^{35}Cl on SOD metal derivatives and SOD with mutations in the substrate-binding cavity, valuable insights were obtained regarding the interaction of the protein with substrate-mimicking and other anionic compounds such as CN^- , N_3^- , NCO^- , NCS^- , F^- , Cl^- , H_2PO_4^- , and HCO_2^- .^{2,90,100,101,105–110} The accessibility of the Cu site in native and mutant $\text{Cu(II)}_2\text{Zn(II)}_2\text{SOD}$, and the effect of anion binding on it, has also been studied by measurements of the paramagnetic effect on the relaxation properties of solvent water.⁹⁰ The picture that arises from these studies is that some anions (in order of decreasing efficiency $\text{CN}^- > \text{N}_3^- > \text{NCO}^- > \text{NCS}^-$) bind to the Cu ion and displace a semicoordinated water molecule, thus reducing the solvent accessibility and affecting one of the Cu–His bonds. The effects of F^- and Cl^- binding are still smaller, making it questionable whether they bind to the Cu ion or to residues in its environment; phosphate and formate do not bind to the Cu ion but to residues near the copper. In addition to the Cu ion, one Arg and two Lys residues in the substrate-binding cavity have a particular effect in determining the affinity of SOD for anions.

3.2 Amine Oxidase (AO)

The eukaryotic copper-containing amine oxidases are dimeric metalloenzymes (M_r 170–190 kDa)¹¹¹ that have various functions, amongst others, in the metabolism of biogenic primary amines. Per dimer they contain two type-II Cu sites and one covalently bound organic cofactor with a quinone functionality. NMR studies of the protein have been confined to this cofactor and its orientation relative to the Cu site(s). ^1H NMR characterization of a small peptide from bovine serum AO that contained the phenylhydrazone-derivatized cofactor revealed it to be 6-hydroxydopa.¹¹² Using several fluorine-labeled phenylhydrazine derivatives, the distance between the organic cofactor at the amine-substrate-binding site of porcine plasma AO and one of its Cu(II) ions was inferred from the effect the paramagnetic Cu(II) exerts on the relaxation behavior of the fluorine nuclei as measured by ^{19}F NMR spectroscopy.¹¹³ The organic cofactor and the Cu(II) ion appear to be within approximately 9 Å from each other.

3.3 Copper-Storage, -Transport and -Resistance Proteins

Several proteins involved in the storage and delivery of Cu ions, as well as in protection against Cu overload, are known. NMR reports concerning the Cu-containing forms of these proteins are scarce. Two examples which have been studied by NMR spectroscopy may be mentioned. In yeast, a 53-residue metallothionein (MT) involved in Cu resistance binds copper as Cu(I). Complete sequential ^1H NMR assignments have been made for the Cu(I)-containing MT as well as for the Ag(I)-substituted form.¹¹⁴ The ligation pattern of the

metal ions was derived from heteronuclear $^1\text{H}\{^{109}\text{Ag}\}$ HMQC spectroscopy.^{114,115} It is noted that the 3D structures of several mammalian MTs have been determined with homo- and heteronuclear 2D NMR spectroscopy using the ^{112}Cd - or ^{113}Cd -substituted proteins.¹¹⁶

As a second example, the interaction of the high- M_r blood plasma protein albumin (67 kDa) with Cu(II), Co(II), and Ni(II) ions has been investigated by 1D and 2D ^1H NMR spectroscopy.^{117,118} It appeared to be possible to detect such interactions at the mobile N-terminus, for which relatively sharp resonances are observed in the ^1H NMR spectrum of the metal-free protein.¹¹⁹

3.4 Other Cu Proteins

A very limited number of NMR reports on other Cu proteins or related model compounds has appeared in the literature. Here we mention two NMR studies that are concerned with Cu sites that have not been dealt with so far in this review. First, crystalline bovine heart cytochrome *c* oxidase (M_r 200 kDa), that contains so-called Cu_A and Cu_B sites, has been studied by solid state ^{13}C NMR spectroscopy.¹²⁰ The spectral resolution appeared to be better than that of dissolved or lyophilised samples and to be comparable with that of crystals of the much smaller protein lysozyme, without severe interference from the paramagnetic metal ions. Measurements of T_1 indicated that the backbone of cytochrome *c* oxidase is more flexible than that of lysozyme. Second, it has been reported that a dicopper dioxygen model compound for the dinuclear type-III Cu site in high- M_r metalloproteins such as hemocyanin exhibits very normal looking ^1H and ^{13}C NMR spectra, indicating strong coupling between the Cu(II) ions.¹²¹

Biographical Sketches

Gerard W. Canters. *b* 1940. M.A., 1966, Amsterdam University (with G.J. Hoitink), Ph.D., 1969, University of Nijmegen, The Netherlands (supervisor Bert de Boer). Postdoctoral work with Charles. S. Johnson, Jr. at University of North Carolina, Chapel Hill, NC, USA and with John van der Waals, Physics Department Leiden University. Lecturer, senior lecturer and Professor of Biophysical Chemistry subsequently at the Physics, Organic Chemistry, Inorganic Chemistry, and Biochemistry Departments of Leiden University, 1973–present. Visiting scientist, Oxford University, UK, 1981–82. Approx. 125 publications. Current research interest: structure/function of metalloproteins and engineering of metal sites in proteins.

Mart van de Kamp. *b* 1963. Ph.D. (supervisor Gerard W. Canters) 1993, Leiden University, The Netherlands. Postdoctoral work at the Nijmegen SON Research Centre with Cornelis W. Hilbers and Frank J. M. van de Ven. Approx. 20 publications. Research specialties: application of high-frequency NMR spectroscopy to the study of copper-containing proteins and modified polypeptides in solution.

1 INTRODUCTION

In this article, we deal with organic compounds which, unlike amino acids or nucleic acids, have no repeating units. By far the major objective in this area evolves around structure determination using all available modern NMR techniques to gain maximum structural information, frequently on microgram scales. In the solution NMR of natural products, the spin system to be elucidated has many spins coupled to each other via the various spin-spin coupling pathways. UV and IR, the first spectroscopic tools used in structure determination of natural products, were introduced in the 1940s. Prior to this period, structural studies were performed by a combination of chemical derivatization, degradation, and synthesis; these reactions always had to be submitted to elementary analyses and determination of molecular weights in order to check whether the reactions had proceeded as expected. Hence, proof for the presence of a hindered ketone or hydroxyl group could be time-consuming and was frequently the subject of a full communication. The structure determination of cholesterol required several decades until it was finally solved in the early 1930s with the help of X-ray, one of its earliest applications.

In the 1950s, solution ^1H NMR became available to organic chemists, and soon became the most popular and important method for determining organic structures because it readily provided much information about connectivities between hydrogen atoms, usually the most abundant nucleus in organic compounds. Subsequent developments of Fourier-transform NMR facilitated measurements of insensitive nuclei present in low natural abundance, e.g., carbon-13 or nitrogen-15.¹ Two-dimensional Fourier transform NMR, which correlates spin pairs through various kinds of interactions, drastically increased the amount of structural information one could secure.^{2,3}

Topics in natural products are increasingly expanding into interdisciplinary areas such as elucidating the mode of action

of bioactive compounds, which in turn almost invariably requires an understanding of the interaction between ligand and biopolymeric receptors on a molecular structural basis. The recent techniques of multidimensional NMR and solid state NMR will play crucial roles in such studies. This article describes some general approaches and examples in natural products NMR from a methodological point of view.

2 SAMPLE PREPARATION

Natural products are usually analyzed by solution NMR, some of the common solvents being deuterated chloroform, benzene, and deuterium oxide. When carbon tetrachloride or water is the solvent, it is advisable to add about 5% of a deuterated solvent, which maintains a high stability and homogeneity of the magnetic field by the so-called deuterium 'lock system'.

In order to obtain high-resolution spectra, undissolved material and contaminants such as fibers must be removed by filtration upon addition of the solution to the sample tube. It is also critical to have a homogeneous solution and to pay attention to minuscule iron particles coming from spatulas because of their deleterious effects on spectral resolution. When measuring nuclear Overhauser effects (NOE), a preliminary degassing step is essential because it removes interfering paramagnetic species such as oxygen gas. The degassing process is performed by repetition of the steps of (i) submitting the frozen solution to reduced pressure, and (ii) bringing the solution to room temperature. If possible, it is advisable to seal the sample tube under high vacuum. However, it is very difficult to carry out protocols (i) and (ii) with water or deuterium oxide solutions due to the big difference in volume between the frozen state and solution. Without proper precaution this may lead to breaking the NMR sample tubes.

The selection of the solvent is particularly important for NMR measurements. Usually the sample can be recovered from the NMR tube without decomposition, but this naturally depends on the stability of the compound in the solvent. For example, traces of HCl and phosgene are generated by the decomposition of chloroform, and this often initiates chemical reactions or sample decomposition. Especially if tube-sealing has not been done properly, chloroform vapor at the tube tip generates considerable acid by heat. When using chloroform for an unstable sample, the solvent should be filtered through a neutral aluminum oxide column just before sample dissolution, and the sample removed as soon as possible after measuring. Other solvents such as benzene- d_6 or dimethyl sulfoxide- d_6 (DMSO- d_6) are also common solvents. Benzene- d_6 has less solubilizing properties than chloroform but exhibits unique solvent effects in that the chemical shifts of the protons are drastically shifted. Hydroxyl and amide protons, including the coupling pattern, can be observed in strongly solvating solvents such as DMSO- d_6 and tetrahydrofuran; however, recovery of the sample from DMSO- d_6 is more tedious.

The common chemical shift references in both ^1H and ^{13}C NMR are usually tetramethylsilane (TMS), 3-trimethylsilylpropionic acid- d_4 sodium salt (TSP), etc. The residual proton or the carbon peak in the solvent can also be used as a reference. However, since this chemical shift changes slightly according to sample concentration or temperature, the use of an internal standard is strongly recommended.

3 CHEMICAL SHIFT AND SPIN-SPIN COUPLING

In structure determinations of natural products, the chemical shift is one of the most important pieces of information.⁴ For example, a peak around δ 9.5 in the ^1H NMR spectrum strongly suggests the existence of an aldehyde or a formyl group, which can be readily checked by other routine NMR techniques such as ^{13}C NMR and $^1\text{H}/^{13}\text{C}$ decoupling. Spin-spin coupling also provides vital information regarding the connectivities of protons.

3.1 ^1H NMR

Many ^1H NMR peaks have chemical shifts or shapes characteristic of a particular functional group. For example, a *t*-butyl group exhibits an intense nine-proton singlet, whereas three-proton singlets are exhibited by freely rotating (methyl) Me groups (on the NMR timescale) which are present in methyl, methoxyl, and acetate groups; a Me group shows simple and distinguishable signals because it has only three types of spin-spin coupling patterns, i.e., singlet, doublet, and triplet. The chemical shifts of steroidal 10- and 13-Me groups were studied extensively in the early days leading to additivity rules reflecting nearby substituents.⁵ Methylene and methine spectra give rise to far more complex features due to the broad range of chemical shifts and various spin-spin coupling patterns.⁶ The chemical shifts of protons in a cyclic compound show subtle differences depending on ring current and conformational effects. For example, the protons in cyclohexane absorb at δ 1.44. However, if the ring is fixed in the chair conformation, the equatorial protons absorb at δ 1.6, whereas the axial protons absorb at the lower frequency (higher field) of δ 1.2 because of the ring current. Olefinic and aromatic protons also cover a wide range of chemical shifts, some being predictable by empirical rules.^{7,8}

NMR techniques such as COSY and HOHAHA (TOCSY) enable one to clarify the correlation between chemical structure and spin systems starting from a specific peak. Furthermore, the nuclear Overhauser effect provides information regarding proximate protons.

3.2 ^{13}C NMR

The ^{13}C NMR chemical shift covers a wide range exceeding 250 ppm and is dominated by a paramagnetic term arising from the asymmetric p-orbital in chemical bonding. The decoupling of protons leads to simple singlet peaks, because the natural abundance of ^{13}C is 1.1% and the height of doublet peaks due to ^{13}C - ^{13}C spin-spin coupling is only 0.55% for the center peak. On the other hand, the low natural abundance of ^{13}C is advantageous for biosynthetic studies since the use of precursors specifically enriched with ^{13}C allows one to locate its position; when two ^{13}C atoms become incorporated in adjacent positions, this can also be readily detected and analyzed through the characteristic coupling pattern. Because of the difficulty in theoretical calculations of ^{13}C chemical shifts, certain empirical rules or comparisons with known compounds are used for chemical shift predictions.⁹

Determination of the multiplicities of respective carbon signals is an important first step in the assignment of

signals and structure determination of natural products. Proton-coupled carbon spectra and off-resonance techniques have been used for such purposes. However, because these methods have resolution problems, polarization transfer techniques, such as INEPT or DEPT, are more commonly used.¹⁰⁻¹³ Furthermore, an almost complete correlation between protons and carbons can be obtained from two-dimensional NMR techniques, ^1H - ^{13}C COSY (HETCOR), HMQC (^1H -detected heteronuclear multiple quantum coherence), or HSQC (^1H -detected heteronuclear single quantum coherence).^{2,3,14-16} The next step is to clarify the arrangement of carbons and protons in the molecule. Long-range proton/carbon spin-spin coupling provides this kind of information; for this purpose, many techniques such as LSPD (long range selective proton decoupling), COLOC (correlation spectroscopy via long range coupling), and HMBC (^1H -detected multiple bond heteronuclear multiple quantum coherence) have been developed.¹⁷⁻¹⁹

3.3 Other Nuclei

Natural products contain oxygen, nitrogen, phosphorus, sulfur, and metals. Generally, oxygen and nitrogen are not detected because of their low sensitivity. However, phosphorus has good sensitivity and a spin quantum number of $\frac{1}{2}$, so that ^{31}P NMR is commonly used for the characterization of phosphorus groups.

3.4 Chemical Manipulations

The combination of chemical manipulations with NMR measurements is an important aspect that greatly simplifies structure determination, but is frequently underutilized. Taking the hydroxyl group as an example, manipulations involve acetylations, substitution of the hydroxyl proton with deuterium oxide, usage of solvating solvents to differentiate among primary/secondary/tertiary hydroxyl groups, addition of shift reagents, etc.

The addition of deuterium oxide in ^1H NMR often causes the disappearance of spin-spin coupling between the hydroxyl proton and its adjoining proton. In ^{13}C NMR it induces an isotope shift on the OH-bearing carbon; such data readily differentiate hydroxyl and ether groups.²⁰ However, since the isotope shift in ^{13}C NMR is rather small, an internal reference or a coaxial tube is required.

Acetylation induces a ca. 1 ppm high-frequency shift on the adjoining proton of a hydroxyl group; acetylation using deuterated acetic anhydride prevents interference from the intense acetate methyl peaks around δ 2 so that other weaker signals can be analyzed. Benzoylation can also be used for similar purposes; an advantage of using benzoate derivatives is that whenever applicable, measurements of CD spectra will determine the absolute configuration through exciton coupling.²¹

When the solvent is changed from chloroform-*d* to benzene-*d*₆, some protons undergo large low- or high-frequency shifts. This shift, the ASIS effect (aromatic solvent induced shift), is due to the diamagnetic current effect of the solvent. ASIS and shift reagents are used to separate overlapping proton peaks.

Figure 1 Structure of palytoxin (**1**) and oxidative cleavage fragments. Fragments resulting from ozonolysis and periodate cleavage are bracketed with solid and dotted lines, respectively. A, B fragments: NaBH₄ reduction of the partial ozonolysis products of *N*-(*p*-bromobenzoyl)palytoxin. C fragment: NaBH₄ reduction of the complete ozonolysis product of palytoxin. D, E fragments: NaBH₄ reduction of the NaIO₄ degradation products of palytoxin. F fragment: NaIO₄ degradation of palytoxin

3.5 Example 1: Palytoxin

Palytoxin (**1**) is a marine toxin obtained from *Palythoa* soft corals, and is one of the strongest neurotoxins. The biological activity of this toxin is thought to be related to the sodium channel. The structure determination was carried out by two groups, Uemura/Hirata in Nagoya (Japan)²² and Moore in Hawaii (US).²³ Its complex structure is shown in Figure 1.

Uemura and Hirata secured the smaller fragments more suited for structure determination by ozonolysis and periodate oxidation; the terminal aldehyde groups in the resultant mixture were reduced by sodium borohydride to obtain stable fragments. After acetylation and purification, these fragments were mainly analyzed by ¹H NMR. It was not easy to establish the structure around C-47, i.e., to differentiate between (**1a**) and (**1b**) (Figure 2); this was finally solved by comparing the ¹³C chemical shifts with those of the model compounds (**2**) and (**3**), which led to the six-membered hemiketal moiety. The Moore group also carried out extensive NMR studies.²³

This molecule has 64 asymmetric centers, in which 13 centers were determined by X-ray crystallography. However, the preparation of derivatives with fixed conformations would have been necessary in order to determine the relative configurations of the remaining 51 asymmetric centers, an almost impossible task to perform because of the availability of the sample. The configurations of these asymmetric centers were finally established by synthesis of the fragments.²⁴

3.6 Example 2: Brevetoxin A

Brevetoxins (BTX) are potent neurotoxins produced by blooms or explosive growth of the dinoflagellate, *Gymnodinium breve* Davis (*Ptychodiscus breves* Davis), the 'red tide'. The toxins have led to massive fish kills, mollusk poisoning, and human food poisoning along the Florida coast and the Gulf

Figure 2 ¹³C NMR of C-47 in palytoxin: (a) structural alternatives (**1a**) and (**1b**) of the hemiketal portion in palytoxin; (b) model compounds (**2**) and (**3**)

Figure 3 Structures of brevetoxin (BTX)- A (4) and -B(5); protons of ring E of BTX-A (indicated by the arrow) were detected by a HOHAHA experiment

of Mexico. Structures of two of the isolated toxins BTX-A (4) and BTX-B (5) are shown in Figure 3.

A variety of two-dimensional NMR techniques were used in the structural studies of 10 mg BTX-A, $C_{49}H_{70}O_{13}$.²⁵ COSY is a popular method for clarifying spin–spin coupled systems, and many variations have been developed. TOCSY or HOHAHA, related to the spin lock method, is a further method developed to observe broad or weak signals as well as relay peaks. The COSY pulse sequence used during the early stages of BTX-A structural studies provided good spectra of the terminal parts of the molecule. However, the mobile conformation of the eight- and nine-membered rings E/F/G in the middle of the molecule broadens the proximate proton signals, and it was difficult to observe the broad peaks in the COSY spectrum. These difficulties were overcome in the HOHAHA spectrum which now showed cross peaks related to the broad signals and the various kinds of relay peaks. Such NMR data, coupled with systematic analysis of the MS data, led to structure (4) (however, with a 6α -Me).²⁵ Independently, Shimizu, Clardy and co-workers determined the structure of BTX-A (4) by X-ray crystallography;²⁶ the NMR and MS-deduced structure had only to be corrected for the 6-Me configuration.

3.7 Example 3: Brevetoxin B

The ^{13}C labeling technique is extremely powerful for investigating the biosynthesis of natural products, because the labeled position is easily determined from the assigned ^{13}C NMR spectrum. Generally, it is necessary to use several kinds of carbon-13 labeled precursors for the elucidation of biosynthetic pathways. If a doubly-labeled compound with two adjacent carbon-13 nuclei is available, such as $^{13}CH_3^{13}COOH$, the position of the incorporated precursor can be recognized through spin–spin coupling. The ^{13}C INADEQUATE technique is very useful for such purposes because the intense singlet peaks which arise from single quantum transitions are

Figure 4 Biogenesis of brevetoxin B (5): the C_2 units that originate from the same acetates are enclosed in squares; m and c denote, respectively, the carbons derived from the methyl and carboxy carbons of acetic acid

suppressed by double quantum filtering. ^{13}C INADEQUATE is one of the ideal techniques to trace the connectivities of the carbon skeleton in a molecule. A major problem, however, is that the sensitivity level of this experiment is too low for this pulse sequence to be used routinely because of the low natural abundance of carbon-13; about 100 mg of sample would be necessary for mapping out the skeleton of a steroid using currently available instruments. However, the method becomes extremely powerful with ^{13}C -labeled compounds even if the incorporation level is low (several per cent).

Brevetoxin B (BTX-B) (5) also has a linear polycyclic structure which is related to, but different from, the carbon skeleton of BTX-A (Example 2). The assignment of the ^{13}C NMR spectrum of BTX-B was performed by a combination of the 1H – 1H COSY, DEPT, 1H – ^{13}C COSY (HETCOR) and COLOC techniques.²⁷

The biosynthesis was studied by ^{13}C NMR measurements of samples enriched with $[1-^{13}C]$ -, $[2-^{13}C]$ -, $[1,2-^{13}C_2]$ -acetates and methyl- ^{13}C -methionine.²⁷ The *Gymnodinium breve* Davis (*Ptychodiscus brevis* Davis) culture (18 L) yielded approximately 1–2 mg of BTX-B and 0.5–0.8 mg of BTX-A. From the ^{13}C NMR peak heights, the incorporation level of acetates in BTX-B was estimated to be 2.0–2.5%. The 2D INADEQUATE measurements on BTX-B (5) incorporating $[1,2-^{13}C_2]$ acetate enabled one to confirm assignments of many carbons as well as to elucidate their biosynthetic origins as shown in Figure 4. In this case, the ^{13}C -incorporation pattern shows that the single carbon chain which constitutes the backbone of the ladder-like oxacyclic skeleton is not a simple polyketide. Chou and Shimizu carried out extensive biosynthetic studies of BTX-B using ^{13}C NMR, and obtained evidence for the mixed origin of the backbone carbon chain.²⁸

4 NUCLEAR OVERHAUSER EFFECT

When an appropriate nucleus is perturbed by saturation or inversion, the intensity of other nuclei which are close to that perturbed may be changed. This is a relaxation phenomenon based on the dipole–dipole interaction, and is called the nuclear Overhauser effect (NOE).²⁹ It has become an indispensable technique in structural studies of natural products because it yields information on a pair of proximate nuclei. The sign of the intensity change depends on the relationship between the molecular motion and the observing

frequency. Thus, a small molecule in a low viscosity solvent is usually in the ‘extremely narrowing condition’, and shows a strong positive NOE, i.e., enhancement in signal intensity. However, the combination of a bigger molecule (MW > 1000 Da), a viscous solvent, and a high observation frequency results in a ‘diffusion limit condition’, and gives rise to a negative NOE. The intermediate state of these conditions is a no NOE. Under such conditions, the temperature, solvent, or magnetic field strength should be changed. The use of the ROESY experiment is also a good solution.³⁰

4.1 Steady-State NOE and Difference Spectroscopy

Steady-state NOE is usually used for small molecules because the intensity of the NOE is positive and weak. In such cases, it is usually unnecessary to consider spin diffusion, and one secures qualitative data that disclose the spatial relationships of certain groups within the molecule. The NOE difference spectroscopy technique is used to observe explicit intensity changes.

4.2 NOESY

For the global search of NOE pairs and quantitative treatment, the NOESY experiment which is related to the transient NOE method is used.^{31,32} The cross-relaxation term can be obtained upon changing the mixing time. A positive NOE spectrum shows opposite phases between diagonal peaks and cross peaks, so that the chemical exchange peaks are easily distinguished from NOE peaks. On the other hand, a negative NOE and a chemical exchange spectrum show the same phase in the diagonal and cross peaks. To distinguish these, the ROESY experiment is used.

4.3 Example 4: Ginkgolide

Ginkgolides are diterpenoids obtained from the root bark of *Ginkgo biloba* L. (ginkgo tree) which is the last surviving member of a family of trees that appeared more than 200 million years ago.³³ The compounds have a unique cage structure possessing a *t*-Bu group in the molecule. The ginkgolides were the first example of the use of NOE in the structure determination of natural products. The NOE was first discovered by Solomon in his study of the relaxation mechanism of the two-spin system HF.³⁴ Then, Anet and Bourn demonstrated the first example of intramolecular homonuclear NOE in simple organic compounds in 1965.³⁵ At about the same time, during the course of scrutinizing small spin–spin couplings in the ginkgolides, Woods and co-workers observed that irradiation of the *t*-Bu group led to an increase in the intensities of certain proton peaks.³⁶

As shown in Figure 5, four protons were affected by saturation of the *t*-Bu group in ginkgolide C (6). Later, this phenomenon was interpreted to be the same as Anet’s finding. The affected protons were identified as being close to the *t*-Bu group, and this finding culminated in the structure determination of the ginkgolides.³⁴

(6) Ginkgolide C: $R^1 = R^2 = R^3 = OH$

Figure 5 NOEs of ginkgolide C (6): NOEs (indicated by arrows in the structure) observed upon irradiation of the *t*-Bu group

4.4 Example 5: Taxane Derivatives

Soon after the initial observations of NOE, it was applied in the structure determination of various naturally occurring taxanes [TB (8), TE (9), TJ (10)].³⁷ These compounds are diterpenoids isolated in only very small amounts from the leaves of *Taxus cuspidata* Sieb. *et* Zucc. The molecular weight of the compounds is in the range of 664–704 Da, so that the compounds fall within the extreme narrowing condition and the NOEs are positive.

As shown in Figure 6, the NOEs between H-2/H-5 and 15-Me, and between H-10/12-Me and H-10/H-7 clearly distinguish orientations of the protons with respect to the taxane skeleton. The remarkable NOE observed between 12-Me and the cinnamate H-21 not only determined the configuration at C-5 but also demonstrated that the ester group was tucked under, like the tail of a shrimp. This example shows that proximate pairs may exist in a molecule, even when they are distant from each other in the planar structure.

4.5 Example 6: Vancomycin

Vancomycin (11) is a broad-spectrum antibiotic produced by *Streptomyces orientalis*, which inhibits the growth of cell walls

Figure 6 (a) Planar structures of taxinine (7), and taxinines B (8), E (9), and J (10); (b) NOEs (indicated by arrows) observed in taxinines B, J, and E

by the recognition of a terminal D-alanyl-D-alanine functional group. This 1449 Da molecule contains disaccharide, phenol, and amino acid groups and also chlorine atoms. At first, the structure was analyzed by X-ray crystallography using the degradation product of vancomycin, CDP-1 (**12**).³⁸ The observed NOEs were negative because the sample was dissolved in the viscous solvent DMSO and measured at high frequencies (270 MHz or 400 MHz) which matched the spin diffusion limit condition.³⁹ This is probably the first example of the observation of a negative NOE in the natural products.

Williamson and Williams paid careful attention to spin diffusion and spin migration (chemical exchange), and measured the build-up rate of NOEs. From such data, the distances between protons in some pairs of protons were estimated; it was determined that one of the aromatic rings containing chlorine (ring C) had an inverted conformation (Figure 7). In this study, it was found that CDP-I (**12**) (structure determined by X-ray diffraction) had an isomer in which the conformation of ring C was the same as that in vancomycin, from which it was interpreted that the strong steric hindrance present in ring C resulted in bond-breaking and bond-reforming at the P6- α 2 bond to yield the conformational isomer of CDP-1.

5 MULTIDIMENSIONAL NMR

Two-dimensional NMR was developed by the addition of evolution and mixing times; the detection period is one

of the time dimensions.⁴⁰ The substitution of the detection period by a two-dimensional pulse sequence leads to three-dimensional NMR. Repetition of the same procedure results in higher-dimensional NMR. The multidimensional technique is expected to improve the separation of overlapping peaks, thus leading to greater facilitation in complex signal assignments. However, in this technique, since multiple evolution and mixing periods are present, the signal-to-noise (S/N) ratio problem becomes severe and requires the use of labeled samples. If the problem of low S/N ratio is solved, the technique promises to be a very powerful tool for the structure determination of complex natural products (and especially biopolymers).

5.1 Example 7: Maitotoxin

Maitotoxin (MTX) (**13**) with a molecular weight of 3422 Da and an empirical formula of $C_{164}H_{256}O_{68}S_2Na_2$ is one of the largest natural products.⁴¹ The toxicity of MTX, which is related to the stimulation of calcium influx into cells, is also remarkably strong (1 mg of MTX kills 1×10^6 mice). MTX was first identified as a toxic substance of the cigatera of surgeon fish collected in French Polynesia, but it was subsequently found that *Gambierdiscus toxicus* produced this toxin in cultures.

Structural determination was carried out relying mainly on modern physicochemical methods such as MS/MS and multidimensional NMR (Figure 8). Various kinds of two-dimensional techniques, e.g., double quantum filtered correlated spectroscopy (DQF-COSY), NOESY, 1H - ^{13}C COSY (HETCOR), HMQC, and HSQC, were used to obtain valuable information. However, the signal overlap was so severe that a three-dimensional NMR technique was used for spectral editing and resolution enhancement. Murata et al.⁴¹ cultured *G. toxicus* in a medium containing 0.01% (w/v) of 99% ^{13}C -enriched sodium carbonate, to produce 9 mg of 4% ^{13}C -enriched MTX from 2000 L of the culture.

The NOESY-HMQC data were acquired as a three-dimensional matrix [$t_1(^1H)$ 128, $t_2(^{13}C)$ 32, $t_3(^1H)$ 512] during a period of 6 d. The region which has over 1000 NOE peaks in the two-dimensional spectrum is resolved in 64 2D sheets, in which only 70 nonoverlapping cross peaks were obtained at 77.5 ppm (carbon chemical shift) as shown in Figure 9. These data were extremely helpful in elucidating the NOE correlation.⁴² The experiment was performed with the pulsed field gradient technique, which simplified the pulse sequence and reduced the running time.

6 SOLID STATE NMR

Solid state NMR has not been used in structure determinations of natural products because of experimental difficulties. However, recent progress has made it possible to obtain unique information such as nuclear distances and dynamics of the molecule. Furthermore, as more attention is being paid to elucidating the function of natural products in the biological system, solid state NMR will undoubtedly become an increasingly useful tool in the chemistry of natural products.

6.1 Example 8: Retinal (1)

Bacteriorhodopsin (bR) is a transmembrane protein possessing a light-driven proton pump function, and is produced by *Halobacterium halobium*. The protein has a retinal chromophore which binds to lysine 216 (Lys-216) via a protonated Schiff base linkage. Because bR can be readily grown, is a light-driven proton pump, and is one of the simplest of the membrane proteins, it has been the subject of extensive investigations in all fields of science. In natural product chemistry, numerous retinal analogs have been incorporated into bR in order to elucidate its function in the protein. Recently carbon-13 labeling and solid state NMR methods have been applied

to bR to determine the configurations and conformations of the chromophore. The retinal chromophore labeled by ^{13}C at C-8 and 5-Me is bound to the protein. Magnetization transfer experiments under rotational resonance conditions ($\delta = n\omega_r$, where δ is the isotropic shift difference, ω_r is the magic angle spinning speed, and n is a small integer) were used to determine the distance between the ^{13}C atoms at C-8 and 5-Me [indicated by large black dots in (14) in Figure 10]. The 4.2 Å distance established the 6-*s-trans* conformation (14) of the retinal moiety (Figure 10); if it were 6-*s-cis* (15), the distance would have been 3.1 Å.⁴³

The C-14 carbon of retinal and the ϵ carbon of Lys-216 in the protein were labeled with ^{13}C , and the distance between these carbons was measured by the same method. The distances were 3.0 ± 0.2 Å for the dark-adapted bR₅₅₅ (16) which leads to a *syn* C=N bond, and a 4.1 ± 0.3 Å distance for the light-adapted bR₅₆₈ (17) which leads to an *anti* C=N bond (Figure 11).⁴⁴

Figure 11 Structures of the retinal chromophore in dark-adapted bR₅₅₅ (16) and light-adapted bR₅₆₈ (17)

6.2 Example 9: Retinal (2)

Solid state deuterium NMR yields information on molecular conformation and dynamics through quadrupole coupling. A bR sample was regenerated from a ²H₁₁-retinal carrying the multiple labels 1-CD₃, 1-CD₃, 2-D, 4-D, 4-D, and 5-CD₂H. The sample was prepared as an uniaxially oriented membrane patch, and the axis was systematically changed with respect to the magnetic field. The quadrupole splittings showed that the two Me groups on C-1 have angles of $94 \pm 2^\circ$ and $75 \pm 2^\circ$ with respect to the membrane, respectively, and that the third Me group on C-5 is directed toward the cytoplasmic side with an angle of $46 \pm 3^\circ$. This indicates that the orientation of the cyclohexene ring is almost perpendicular to the membrane surface and has a 6-*s-trans* conformation around the C-6/C-7 bond (Figure 12).⁴⁵

Figure 12 The ²H₁₁-retinal chromophore incorporated into bR

1 INTRODUCTION

During the past two decades solid state NMR spectroscopy and its applications have grown rapidly among the chemistry and biochemistry community. The availability of increasingly sophisticated instrumentation and software has created opportunities for conducting experiments in areas that have not previously been available to the general chemical community. These new opportunities have been especially helpful in the study of solids. While the majority of such solid state applications have utilized ^{13}C nuclei, a much broader range of interesting nuclei (e.g., ^{11}B , ^{14}N , ^{15}N , ^{17}O , ^{19}F , ^{23}Na , ^{27}Al , ^{29}Si , ^{31}P , ^{113}Cd , ^{209}Pb , etc.) has emerged for use by solid state scientists and engineers.

Interest in magnetic resonance studies of nitrogen has increased significantly in the past decade. The distribution of nitrogen containing substances in materials important to the chemical, biological, medical, agricultural, and environmental sciences is well documented. The ^{14}N nucleus (99.6% natural abundance, nuclear spin 1) is quadrupolar giving rise to a broad signal while the ^{15}N nucleus has spin 1/2. The relative sensitivity of both nuclei is approximately 1×10^{-3} compared to ^1H . Nitrogen NMR data have been extensively reviewed by Witanowski et al.¹ and by Mason.² Most of the literature describes liquid state isotropic shifts and their relationship to structure elucidation, the importance of solvent effects, and tautomeric equilibria. The combination of a large isotropic shift range, approximately 1350 ppm,¹ and sensitivity to electronic interactions involving the lone pair of electrons make ^{15}N shifts a very sensitive probe of both structural changes and intermolecular interaction.³ These attractive features of the ^{15}N nucleus are off-set by the sensitivity challenges arising from a low natural abundance (0.365%), long relaxation times, small magnetogyric ratio, and a subsequent receptivity factor 2.19×10^{-2} relative to ^{13}C for an equivalent number of nuclei. Hence, much of the data reported has been obtained from ^{15}N

labeled materials although modern high field spectrometers have proven their value in studies at the natural abundance level. A significant amount of attention has recently been focused on the role of nitrogen in biological structures⁴ because of its sensitivity to both hydrogen bonding and intermolecular and long-range interactions. In this document the discussion will be restricted to the ^{15}N nucleus.

2 CHEMICAL SHIELDING

The well known relationship between magnetic field strength B_0 (arbitrary orientation in the z direction), the magnetogyric ratio γ_I of nuclear spin I , and the NMR Larmor frequency ν_0 (in frequency units, Hz) is given in equation (1)

$$\nu_0 = \frac{\gamma_I B_0}{2\pi} \quad (1)$$

where ν_0 is the difference in energy between any two of the allowed states. The magnetic inductive effect at the nucleus is equal to the vector sum of the static magnetic field and an induced magnetization vector arising from electronic currents that exist in the sample. The induced magnetization is proportional to B_0 and the proportionality constant is the sum of the chemical shielding and the magnetic susceptibility of the material surrounding the nucleus of interest. In solids, where rapid motional averaging is absent, all intramolecular currents within the molecule of interest are assigned to chemical shielding. Electronic currents arising from neighboring molecules are assigned to magnetic susceptibility. A more detailed and very useful outline of these interactions is provided by Grant.⁵

The electronic circulation set up by the magnetic induction of the applied field perturbs the effects of B_0 at the nucleus of interest. These electronic currents induce a shielding field, B_s , which may be either paramagnetic or diamagnetic (deshielding or shielding) and this induced field must be added to B_0 in order to obtain the effective field, B_{eff} , experienced by the nucleus of interest (equation (2)).

$$B_{\text{eff}} = B_s + B_0 \quad (2)$$

This effect is portrayed in vector form in Figure 1.

The shielding of the nuclear spin is a tensor quantity, described below, that depends on the electronic environment as well as the molecular orientation in the magnetic field. In solids the molecular orientation is locked into a powder pattern in which the nuclear resonance frequency is a function of the orientation of the microcrystalline particles. The random orientation of these particles leads to broad resonance patterns for each unique nuclear spin. The rich informational content of these powder patterns provides more information about electronic structure than the isotropic shifts observed in rapidly tumbling liquid molecules. Unfortunately, the diversity of the banding arising from multiple unique chemical environments in these broad powder patterns obscures the information content that is available in the isotropic chemical shift. However, the components of the shift tensor in the solid state reveal even more information regarding the subtle differences in electronic and geometrical structural characteristics and

Figure 1 Relationship between the applied field, B_0 , and the shielding field and effective fields (not drawn to scale) B_s and B_{eff}

the various experimental techniques employed to extract this information from solid samples is summarized in Section 3.

The shielding interaction with a nucleus is different for each unique chemical environment or symmetry position relative to the remainder of the lattice structure. Furthermore, the orientation dependence of the magnetic field to the screening currents induced around the nucleus presents an anisotropic environment that can be described by the chemical shift tensor. In principal, a different resonance frequency will be observed for each orientation of the nuclear spin with respect to the external magnetic field and the difference in this screening effect from that of a reference material is defined as the chemical shift. The reference that has emerged in the field is

$$\delta = \begin{bmatrix} \delta_{xx} & \delta_{xy} & \delta_{xz} \\ \delta_{yx} & \delta_{yy} & \delta_{yz} \\ \delta_{zx} & \delta_{zx} & \delta_{zz} \end{bmatrix} \quad (3)$$

external nitromethane ($\delta = 0$) with the convention of negative values for more shielded resonance positions. The chemical shift tensor δ in a general reference frame may be represented by a 3×3 Cartesian matrix that is called a second rank tensor (equation (3)) which can be decomposed into three individual tensors of rank zero, one, and two which are defined as the scalar isotropic chemical shift, the symmetric, and antisymmetric chemical shifts denoted (equation (4)) as

$$\delta = \delta_o + \delta_{\text{sym}} + \delta_{\text{anti}} \quad (4)$$

The isotropic shift, δ_o , of zeroeth rank, is the trace of the Cartesian tensor, e.g., $1/3(\delta_{xx} + \delta_{yy} + \delta_{zz})$, and is invariant to any rotational transformation of the coordinate frame. Hence, δ_o is the only part of the chemical shift tensor that can be measured in solution samples; this the result of rapid tumbling motion of the molecules. The antisymmetric (first rank) and symmetric (second rank,) chemical shifts are given in equations (5) and (6), respectively.

$$\delta_{ij}^{(a)} = \frac{1}{2}(\delta_{ij} - \delta_{ji}) \quad (5)$$

$$\delta_{ij}^{(s)} = \frac{1}{2}(\delta_{ij} + \delta_{ji}) \quad (6)$$

The absence of diagonal elements in the first rank tensor renders these second order infinitesimal shift frequencies immeasurable. The traceless second-rank symmetric matrix contains diagonal elements that can provide first-order anisotropic shifts that add to or subtract from the Zeeman frequencies and are measurable in the NMR spectrum of solids. In the symmetric matrix any change in orientation of the magnetic field in the molecular frame will still leave anisotropic shifts along the diagonal of the transformed second-rank matrix. Unlike the antisymmetric components, the off-diagonal shifts in the symmetric portion of the chemical shift tensor will affect the principal values under the transformations associated with matrix diagonalization.

There always exists some frame in which the matrix in equation (3) is diagonal, in which case the three diagonal elements of the chemical shift tensor are designated as the principal values, δ_{11} , δ_{22} , and δ_{33} . By convention the order of the principal values are given as $\delta_{11} \geq \delta_{22} \geq \delta_{33}$, with δ_{11} representing the highest frequency (least shielded) component. The axis system in which the symmetric chemical shift matrix is diagonal is designated the principal axis system (PAS). The diagonal components are the principle values in the PAS while the remaining three (off-diagonal) terms are the Euler angles which define the directions of these principal values in the molecular frame. Hence, the complete description of the chemical shift tensor requires six elements of the shift tensor. The breakpoints in a powder pattern provide the principal values of the chemical shift tensor. The off-diagonal terms can only be obtained experimentally by tracking the chemical shift of each unique nucleus as a molecule (e.g., a molecule in a single crystal) is rotated in the magnetic field. These data can then be transformed into any of a number of reference frames that can be used to determine the orientation of the tensor in the molecular frame. The details of these experiments and transformations are described in a general outline by Orendt⁶ and in detail by Grant⁵ and Sherwood.⁷

The difficulties associated with growing single crystals and then acquiring the necessary orientational data is daunting, time consuming, and complicated by the reality that acquiring a single crystal of sufficient size for NMR experiments is usually not practical. However, sufficient single crystal data, together with theoretical simulations of the shift tensors, have been acquired to demonstrate that quite good approximations can be obtained for the orientation of the shift tensor principal axis system on the molecular frame.^{8,9} Hence, the various types of experiments that provide only the principal values of the shift tensor on powder samples^{6,10} are sufficient, when combined with appropriate theoretical calculations, to describe the off-diagonal elements which fix the orientation in the molecular frame with reasonable accuracy (see Section 4.3). To date, the majority of chemical shift tensor data appearing in the literature has been restricted to the ^{13}C nucleus and the latest, but somewhat dated, compilation of these data together with available data on ^{15}N shift tensor principal values has been provided by Duncan.¹¹ The acquisition of shift tensor data on solid materials, however, has expanded considerably in the past 10–15 years as line narrowing methods and techniques have become available. A review has described these experimental advances⁶ but additional major advances in multidimensional experiments have recently appeared^{12–14} and are described in another article in this encyclopedia,

Magic-angle Turning Spectra of Solids Involving 5π -pulse Sequences.

Despite the challenges faced with obtaining shift tensor data, new experimental techniques now enable investigators to obtain high quality ^{13}C shift tensor data on molecules containing more than sixty unique carbon atoms¹⁰ and ^{15}N shift tensors at the natural abundance level on molecules containing as many as five nitrogens (guanine)¹⁵ and eight non-equivalent nitrogens in potassium penicillin V.¹³

3 EXPERIMENTAL TECHNIQUES

^{15}N chemical shift tensor data have been reported using five different types of experimental techniques: (1) single crystal studies; (2) analysis of static powder patterns and off-magic-angle spinning on simple ^{15}N enriched heterocycles; (3) analysis of powder patterns utilizing the dipolar interaction between ^1H - ^{15}N or adjacent ^{13}C - ^{15}N labeled pairs; (4) powder patterns obtained by means of dynamic nuclear polarization experiments; (5) two-dimensional experiments such as polarization inversion spin exchange at the magic angle (PISEMA), and the five- π pulse experiment five pi replicated magic angle turning (FIREMAT).

3.1 Single Crystals

A single crystal study of L-hystidine-HCl-H₂O¹⁶ reported the full tensor of the two imidazole nitrogens in the amino acid while a single crystal study of $[1-^{13}\text{C}]\text{glycyl}[^{15}\text{N}]\text{glycine}$ provided the principal values of the ^{15}N tensor and its orientation in the molecular frame.¹⁷

3.2 Static Powders and Off-Magic Angle Spinning

The major portion of the ^{15}N shift tensor data has been obtained by static powder pattern analysis. Illustrative examples of static experiments on ^{15}N -enriched materials include: studies of the various phases of NH_4NO_3 ,¹⁸ protonated and non-protonated species in simple five- and six-member nitrogen heterocycles,¹⁹ porphyrin complexes,²⁰ cation binding in a membrane-bound polypeptide,²¹ substituted benzonitriles,²² off-angle fast sample spinning of an isolated ^{15}N - ^{15}N diazo system,²³ static and off-angle fast sample spinning of substituted pyrazoles,²⁴ secondary structure of peptides containing L-alanine²⁵ and poly(β -benzyl L-aspartate),²⁶ substituted benzonitriles,²⁷ the amide fragment of acetanilide and N-methylacetanilide,²⁸ and the relationship of the δ_{33} principal value to the hydrogen bond length in the glycine residue of some oligopeptides.²⁹

3.3 Dipolar Interactions in Powders

^{15}N shift tensor principal values and their orientation in the molecular frame have been determined through the dipolar interaction between proton and nitrogen dipolar coupling in peptides,³⁰ tryptophan and histidine side chains,³¹ the phenylalanine residue,³² the dipolar tensors for the peptide bond in $[1-^{13}\text{C}]\text{glycyl}[^{15}\text{N}]\text{glycine-HCl-H}_2\text{O}$,³³ peptides of the form N-acetyl $[1-^{13}\text{C}]\text{glycyl}[^{15}\text{N}]\text{-X-amide}$ where

X = glycine, alanine, and tyrosine³⁴ and L $[-^{13}\text{C}]\text{alanyl-L-}[^{15}\text{N}]\text{alanine}$,³⁵ an analytical approach for the determination of the principal value σ_{33} of the amide ^{15}N chemical shift tensor element with respect to the molecular frame,³⁶ studies of the nitroso-groups in nitrobenzene and p-nitroso-N,N-dimethyl aniline (in which a very large CSA anisotropy of 1472 ppm was observed),³⁷ the two-dimensional PISEMA data on $[1-^{15}\text{N}]\text{-2'-deoxyguanosine}$,³⁸ the three-dimensional powder patterns of $^{15}\text{N}_{\epsilon 1}$ -tryptophan and $^{15}\text{N}_{\pi}$ -histidine side chains,³⁹ shift tensor values and orientation in the molecular frame in ^{13}C and ^{15}N labeled uracil.^{40,41}

3.4 Dynamic Nuclear Polarization Experiments on Powders

Hu et al.^{42,43} reported large ^{15}N DNP enhancement factors in benzamide (260, compared to CP data) and greater than 900 in carbazole and were able to compare the principal values of the shift tensors in powdered samples of these two molecules with those obtained by standard cross polarization and single pulse experimental techniques.

3.5 Two-Dimensional Experiments

A variety of two-dimensional experiments designed for separating the isotropic and anisotropic chemical shift information were instrumental in advancing resolution and data analysis of complex molecular systems.⁴⁴⁻⁵⁰ The magic angle turning experiments, first conceived by Gan,⁵¹ paved the way

Figure 2 A two-dimensional natural abundance ^{15}N spectrum is shown in which the isotropic shift spectrum with no spinning side bands is plotted vertically on the left while the isolated spinning sideband patterns for the six resolved peaks are plotted on the right, connected to the corresponding isotropic peaks by guide lines

for development of experimental tools^{12,13} that can reveal an amazing amount of detail regarding CSA in complex molecular systems. Recent modifications to the 5- π pulse experiments, FIREMAT¹³ and 2D-PASS¹⁴ have been particularly exciting in significantly expanding the range and complexity of molecules that can be studied. These two experiments, while related by virtue of a common 5- π pulse sequence for generating the two-D data set, possess important differences that are detailed in Ref.¹⁰ Taking advantage of TIGER data processing in the FIREMAT experiment,⁵² one is able to optimize S/N and resolution in the evolution dimension and obtain high quality ¹³C data on molecules with more than 60 different tensors. The power of the FIREMAT experiment can be seen by examining the ¹⁵N spectrum of penicillin V in Figure 2. Potassium penicillin V has two nitrogen atoms and, at ambient temperature, four molecules per asymmetric unit.¹³ Conformational differences in these molecules split the NH nitrogen into the four peaks shown between -271.7 ppm and -275.3 ppm. The conformational differences do not affect the ring nitrogen to the same extent and three of the resonances are degenerate at -212.5 while the fourth is at -214.0 ppm. The FIREMAT experiment has also been used to obtain ¹⁵N shift tensor data at the natural abundance level on nucleic acid bases,¹⁵ purine,⁵³ and indolazines.⁵⁴

4 RESULTS

4.1 Characteristics of Principal Values in Nitrogen Heterocycles

For convenience in consideration of ¹⁵N shift tensors in organic molecules the discussion will be restricted to nitrogen heterocycles since this general class of compounds is ubiquitous in nature. The relatively simple five- and six-member heterocycles have been shown to provide the framework for understanding the shift tensor data in more complex heterocyclic structures including indolazines, the nucleic acid bases and related compounds. Consideration of ionic species also

Figure 3 Definition of the different types of nitrogen atoms present in five- and six-member nitrogen heterocycles. The terms “n” and “p” represent non-bonded lone pair and protonated or bonded, lone pair, respectively

reflects the effects of hydrogen bonding interactions on the nitrogen shift tensors. This is especially interesting because of the lone pair of electrons. The structures portrayed in Figure 3 provide a useful framework from which to understand the experimental shift tensor data.

It is found that four different types of nitrogen tensors are present in simple nitrogen heterocycles. For convenience, the nitrogens with non-bonded lone electron pairs in five- and six-member rings shall be referred to as **5-n** and **6-n** types (such as pyrrole anion and the non-protonated nitrogens in imidazole and benzimidazole) and protonated **5-p** and **6-p** types (e.g., pyrrole, the protonated sites in imidazole and benzimidazole, the imidazolium cation, and the pyridinium cation).

Figure 4 presents a correlation diagram of the principal values of 12 simple heterocyclic structures. Quantum mechanical calculations were used to assign the orientation of the principal values to the molecular frame and to provide insight into the effects of electronic structure on the chemical shielding. These orientation assignments can be made with reasonable accuracy (estimated error of ± 10 degrees based on work on uracil)⁵⁵ if

Figure 4 Correlation of the ¹⁵N chemical shift principal values in 5- and 6-member heterocycles. The principal values are marked by solid lines, and the symbols indicate their approximate orientation in the molecular frames as described in Figure 5

Figure 5 Orientation of the in-plane principal components in nitrogen heterocycles. δ_r and δ_t are depicted in the figure and lie in the plane of the ring approximately in the tangential and radial directions of the ring. $\delta_\perp$ is perpendicular to the ring. (*J. Am. Chem. Soc.*, published with permission)

sufficient structural data (e.g., crystal structure, bond length,) is available.^{56,57}

A cursory inspection of Figure 4 illustrates the differences in the spans of the principal values of the nitrogen types. That the span of pyridine (622 ppm) is not unique as demonstrated by the span of 4-nitropyridine (674 ppm). In pyridine one observes that the δ_{11} shift component is oriented tangential to the ring, a direction that is also perpendicular to the lone pair (see Figure 6). When the hybridization of the nitrogen is changed from the **6-n** to the **6-p** type either by protonation, alkylation, or by *N*-oxide formation the tangential component crosses over the radial component, thus reducing the span of the shift tensor components by approximately 1/2 (to a range of 338–351 ppm). A similar affect is noted for the **5-n/5-p** case. The span in the pyrrole anion (333 ppm) is reduced to 192 ppm in pyrrole. Comparable effects are noted in each molecular pair studied. The data of Hoelger et al.²⁴ exhibit the same phenomena in the amine/imine pair of nitrogens in substituted pyrazoles.

The orientation of the shift tensor on the molecular frame of the compounds containing **5-n** type nitrogens corresponds to that found in pyridine (**6-n**). The span of the **5-n** tensor

Figure 6 Electron orbitals making the largest contributions to the chemical shift principal components in pyridine. R corresponds to the lone pair in pyridine and R=H, O, or CH₃ in pyridine hydrochloride, pyridine-*N*-oxide, and *N*-methylpyridine. (*J. Am. Chem. Soc.*, published with permission)

components is 337–374 ppm, a range that is nearly identical to that of the **6-p** nitrogens. In a manner similar to that noted for pyridine, protonation of the **5-n** lone pair inverts the order of the radial and tangential components and also significantly reduces (again, by approximately 1/2) the span of the **5-p** type nitrogens (to a range of 172–206 ppm). This reduction of span for the **5-n** and **5-p** species, compared to the respective **6-n** and **6-p** species, may be attributed to the larger degree of localization of the six π -electrons in five-member heterocycles compared with the six-member rings.⁵⁸ The increase of the localization of the π -electrons increases the electronic repulsion energy, thereby increasing the energy gaps corresponding to the $\sigma-\pi^*$ and $\pi-\sigma^*$ orbitals which dominate the paramagnetic contribution to the in-plane components. Thus, the paramagnetic contribution to the in-plane components of the shielding term decreases which reduces the shift tensor span.

The effects of interaction of the lone pair with neighboring atoms, whether bonded or non-bonded, is a matter of extreme interest and will be described in Section 4.3.

4.2 The Nucleic Acid Bases

The simple nitrogen heterocycles can be used as a guide to understanding the electronic structure and intermolecular interactions in the nucleic acid bases. Employing a combination of two-dimensional experimental techniques (PHORMAT, TIGER data processing, and FIRMAT) that were dependent on the complexities of the ¹⁵N spectra, the shift tensors were

Figure 7 Correlation diagram of the ¹⁵N shift tensor principal values in nucleic acid bases. Dashed lines are isotropic shift values

obtained on isotopically enriched adenine, and at natural abundance on thiamine, guanine, and cytosine.¹⁵ The principal values obtained, together with data previously reported on uracil,⁴⁰ are presented as a bar graph in Figure 7 in order to visualize the relationship between the various shift tensor patterns.

The ¹³C and ¹⁵N shift tensor data obtained on purine⁵³ provides a useful model for interpreting the patterns observed in the nucleic acid bases. The purine data were obtained under separate sets of conditions and the position of the tautomeric proton could be definitely identified (by means of the ¹³C isotropic shift data) as residing at either the N-7 or the N-9 position. The interpretation of the data is further confirmed by comparing the purine ¹⁵N data with that of the simple nitrogen heterocycles previously described. In the five- and six-member heterocycles (Figure 4) the span ($\delta_{11} - \delta_{33}$) of the shift tensors of the **5/6-p** nitrogens are of the order of 1/2 that of the **5/6-n** nitrogens (compare, for example, the spans of N-1 and N-3 in benzimidazole in Figure 4). The N-7 and N-9 tautomeric structures in purine mirror this effect and, by comparing the spans of the N-7/9 positions in adenine and guanine (Figure 8), the position of the tautomeric proton is clearly evident in these two compounds. Furthermore, the spans of the N-1 and N-3 tensors in uracil and thiamine clearly indicate that the two labile protons occupy these sites while the cytosine data suggest that N-1 is the preferred site, in accordance with x-ray data. In the case of guanine the shift tensor data is consistent with the proton occupying the N-1 site.

Figure 8 Comparison of shift tensor principal values in purine ring structures. The purine data is taken from Ref.⁹ while the adenine and guanine data were taken from Ref.¹⁵

4.3 Effects of Hydrogen Bonding

The large changes in the shift tensor principal values provide a means for assessing hydrogen bonding in a wide range of heterocyclic ring systems. Using density functional theory (DFT) Facelli³ simulated the shift tensor data in benzamide and these results, together with simulations of uracil,⁴⁰ highlighted the importance of including hydrogen bonding, and in general, intermolecular interactions in the calculation of ¹⁵N chemical shift tensors. Further evidence for the importance of these intermolecular interactions in the calculation of ¹⁵N chemical shift tensors can be found by analysis of these tensors in the series of heterocycles portrayed in Figure 4.

For these compounds the rms error between experimental and DFT calculated values, which did not include intermolecular effects, was approximately 30–40 ppm. This large scatter is approximately an order of magnitude greater than that found in simulated data on polyaromatic hydrocarbons.^{56,57}

Utilizing the imidazole structural information obtained from neutron diffraction data it is possible to improve the chemical shift calculations and to examine the effects of hydrogen bonding on the ¹⁵N shift principal values using a dimer model.¹⁹ The correlation between experimental and calculated shift principal values in imidazole, with and without intermolecular interactions, is shown in Figure 9. The rms error of the predicted shift principal values is 40.9 ppm using an optimized geometry and is 13.8 ppm when the structural data includes the position of the hydrogens in the lattice structure along with the effects of hydrogen bonding.¹⁹ Using the neutron diffraction data without including the intermolecular hydrogen bonding

Figure 9 Experimental versus predicted chemical shift values for imidazole. The DFT method was used to calculate the ¹⁵N shift tensor values using the neutron diffraction structure and including the effects of intermolecular interactions due to hydrogen bonding. The letters r, t, and p refer to the radial, tangential, and perpendicular components of the shift tensors. The legends N/HB and NH/HB designate predictions based on intermolecular interactions due to hydrogen bonding for the **5-n** and **5-p** nitrogens, respectively. (*J. Am. Chem. Soc.*, with permission)

effects produces only a modest improvement in the calculated values over those obtained with the optimized geometry. Introduction of intermolecular effects in the simulation of the nucleic acid bases plays a significant role in improving the correlation of experimental and theoretical result, reducing the rms error by a factor of two.¹⁵ Given the 3–4 fold greater span of the nitrogen shift tensor, a rms error of 14 ppm in imidazole and 16 ppm for the nucleic acid bases compares favorably with the 3–5 ppm rms errors obtained in simulations of ¹³C chemical shift tensors in polycyclic aromatic hydrocarbons based on x-ray structure data.^{56,57}

5 CONCLUSIONS

¹⁵N chemical shift tensors in heterocyclic compounds are very sensitive to the hybridization of the nitrogen atom and changes in the tangential component can vary from 200 ppm to as much as 340 ppm in five- and six-member rings, respectively, when the nitrogen lone-pair hybridization is changed. The changes in the magnitude of the in-plane components are so large that these effects may be useful in probing intermolecular interactions associated with hydrogen bonding in biological systems. It is possible to measure and spacially assign the principal components of the ¹⁵N chemical shift tensors obtained from powder samples in heterocyclic compounds. The assignments of the chemical shift tensor components are critical for analyzing the relationship between the electronic structure and shift tensors. In all the compounds studied, the most deshielded component, δ_{11} , is in the plane of the ring and approximately perpendicular to the plane containing the bonding-antibonding or HOMO-LUMO pair of orbitals with the smallest energy gap. The most shielded component, δ_{33} , is always perpendicular to the plane of the ring, as in the ¹³C tensors of aromatic compounds and is less sensitive to changes in the hybridization of the nitrogen atom than the principal components in the plane of the ring.

Employing modern instrumentation and experimental techniques that have been optimized for obtaining shift tensor data, it is now possible to study nucleic acid materials at the natural abundance level or with isotropic enrichment depending on the relaxation times and spectral complexity. The nucleic acid bases exhibit the same sensitivity to small changes in molecular geometry and environment noted for the five- and six-member heterocycles. Even for nitrogens with similar hybridization, differences as large as 50 ppm are found in corresponding principal shift components. Theoretical techniques now available enable the investigator to simulate the molecular environment with reasonable confidence. The agreement between experiment and theory is highly dependent on the molecular model used in the calculations, and molecular models that include the intermolecular interactions show superior correlation with the experimental values.

1 INTRODUCTION

^{17}O is the least utilized of the NMR active nuclei commonly found in biological systems. While oxygen atoms play an important role in the hydrogen bonding, electrostatics, and hydration of biomolecules, the very low natural abundance (0.037%) and quadrupolar nature ($I = \frac{5}{2}$) of ^{17}O nuclei have hindered the development of ^{17}O NMR as compared with ^1H , ^{13}C , ^{15}N , and ^{31}P NMR in biological systems. Over the last decade, however, the availability of both ^{17}O enriched materials and ever higher field FT NMR spectrometers have led to the utilization of ^{17}O nuclei as probes of biomolecular structure and function, some 40 years after the nucleus was first observed.¹

It is the intention of this article to review the characteristic parameters governing the use of ^{17}O NMR in, and how the behavior of ^{17}O nuclear spin magnetization has been applied to, biological systems. The effects of ^{17}O quadrupolar relaxation on ^{31}P magnetization are also important, but are beyond the scope of this review.

2 ^{17}O NMR PARAMETERS

The detailed quantum chemical description of sites in biologically relevant molecules is, in general, extremely complex. The task is greatly simplified in NMR by modeling nuclear spin interactions as independent of the rest of the system, with time-dependent interactions between spins and the bulk (or lattice) being termed ‘relaxation’. This, and other considerations, allows for the simplification of the ^{17}O NMR of biomolecules to the study of ^{17}O chemical shielding, ^{17}O relaxation (resulting from couplings between the nuclear quadrupole and its local environment), and ^{17}O quadrupole couplings.

The chemical shielding of a nucleus is a function of the electronic structure near the nucleus. ^{17}O nuclei are particularly sensitive to differences in chemical environment;

for example, the two distinct oxygen sites in ozone are separated by 566 ppm.² Differences in chemical shift between sites in a molecule can be used to determine molecular structures, as well as to study dynamical processes in these structures, such as conformational changes, substrate binding, and hydrogen bonding. The ^{17}O chemical shift is commonly referenced to H_2^{17}O in biological NMR studies.

All nuclei with $I > \frac{1}{2}$ have a nuclear quadrupole moment eQ . The interaction of eQ with an electric field gradient eq is quite strong, typically dominating the NMR spectrum of a quadrupolar nucleus. For most biomolecules, the interaction between the eQ of ^{17}O and eq is modulated by rotational motion, either molecular tumbling or internal rotations, making it an efficient relaxation mechanism. In the extreme narrowing limit (very fast motions on the NMR timescale), the nuclear quadrupole relaxation rate essentially determines the resonance linewidth L which can be expressed as

$$L \approx (12\pi/125)(1 + \eta^2/3)\chi^2\tau_r \quad (1)$$

where $\chi = e^2qQ/h$ is the nuclear quadrupole coupling constant, η is the asymmetry parameter of the electric field gradient tensor, and τ_r is the rotational correlation time.³ ^{17}O linewidths are therefore proportional to the square of the electric field gradient at the nucleus, and are generally inversely proportional to the molecular correlation time. This limits the applicability of ^{17}O NMR either to relatively small molecules or to sites in molecules where χ is much less than typically found for ^{17}O nuclei (about 10 MHz, see Kintzinger⁴). Within this limitation, ^{17}O relaxation can be used to measure differences in χ and τ_r for either two sites in the same molecule, or the same site under different conditions. For slow molecular motions ($\tau_r \gg 1/\nu_L$) relaxation is a weighted sum of three exponentials, resulting in deviations from Lorentzian lineshapes, and such effects have been observed experimentally for C^{17}O bound to heme proteins, where χ values are very small (about 1–2 MHz).⁵

3 BIOPHOSPHATES

Biophosphates are involved in many biological processes, such as energy transport and utilization, information storage and retrieval, and membrane structure and transport. Examples of such compounds are adenosine diphosphate (ADP), adenosine triphosphate (ATP), DNA, RNA, and phospholipids.

Tsai et al.⁶ have demonstrated that bridging and phosphoryl ^{17}O resonances in biophosphates can be assigned from their relative linewidths, due to differences in χ between the various sites. Linewidths are all relatively broad, and several groups have demonstrated improved spectral resolution upon sample heating,^{7–11} which decreases τ_r and thereby the ^{17}O linewidths, allowing for more accurate determination of ^{17}O chemical shifts and spin–spin coupling constants, $J(^{31}\text{P}, ^{17}\text{O})$. Gerotheranassis and Sheppard¹¹ also demonstrated the utility of using ^{17}O depleted water to minimize the background H_2^{17}O solvent peak, which in aqueous samples frequently overwhelms the resonance from even an ^{17}O enriched sample.

The pH dependence of the ^{17}O chemical shift has been determined for phosphoryl oxygen atoms in several phosphates, including adenosine monophosphate (AMP), ADP, and

ATP,^{9,10} demonstrating the effect of protonation upon the phosphoryl ¹⁷O chemical shift.

The binding of several diamagnetic ions to ATP has been studied using ¹⁷O relaxation rates.^{12,13} The phosphoryl ¹⁷O linewidth increases markedly upon ion binding, indicating the coordination sites for Mg(II), Co(III), Sc(III), La(III), and Lu(III) in M · ATP_n complexes.

The hydrogen bonding of uridine derivatives has been studied using ¹⁷O NMR.¹⁴ Equilibrium constants and interaction enthalpies of water–uridine hydrogen bond complexes were determined by observing changes in ¹⁷O chemical shift as a function of water concentration, in acetonitrile.

¹⁷O spectra of hemiacetal and aldehydic abasic sites in DNA of importance in DNA damage and repair have been studied,¹⁵ demonstrating the ability to observe approximately 10 μM aldehyde signals in the presence of approximately 20 M solvent ¹⁷O.

4 AMINO ACIDS AND POLYPEPTIDES

The tertiary structures of polypeptides and proteins in aqueous solution are strongly influenced by hydrogen bonding, both within the solute molecule and with the solvent, and ¹⁷O NMR has been used to gain insights into these interactions.

The effects of proton exchange between peptide termini and water on ¹⁷O chemical shifts have been used to probe the electronic structures of amino acids,^{11,16} dipeptides,^{17,18} and peptide carboxamides.¹⁹ The ¹⁷O chemical shift has also been used to monitor the presence of hydrogen bonding in peptide models,²⁰ dipeptides,¹⁸ peptide carboxamide,¹⁹ acylprolines (model β- and γ-turns),^{21–23} and small polypeptides.²⁴

The hydration and aggregation of peptides has been studied using ¹⁷O relaxation measurements. ¹⁷O linewidths of amino acids,^{16,25} dipeptides,¹⁸ peptide carboxamides,¹⁹ and small polypeptides²⁴ have been determined in various solvents, locating hydration sites at carboxylate and carbonyl oxygen atoms, in addition to providing a method of monitoring peptide aggregation. In addition, a ¹⁷O relaxation study of ATP binding to adenylate kinase²⁶ has been reported, demonstrating the feasibility of studying enzyme–substrate interactions via ¹⁷O NMR, providing the ligand is not rigidly held.

¹⁷O chemical shifts have also been found to be torsion-angle dependent in aryl carboxylic esters, acids, and amides,²⁷ and ¹⁷O NMR promises to be a powerful technique for elucidating the structures of membrane peptides and proteins, using oriented samples.

5 CO AND O₂ IN HEMOPROTEINS

The nature of Fe–O₂ and Fe–CO bonding in heme proteins and model compounds has been studied using ¹⁷O NMR. ¹⁷O resonance frequencies and linewidths have been measured for O₂ bound to Vaska's compound,²⁸ O₂ bound to picket-fence and basket-handle porphyrin model compounds,^{29–31} CO bound to peroxidases,³² as well as other hemoproteins,^{5,33} and O₂ bound to hemoproteins in the solid state.³¹ Results were found to be in general agreement with Pauling's ideas of end-on bonding, with additional electrostatic field effects being proposed to take into account the chemical shift variation seen

from protein to protein.³⁴ In Fe–O₂ systems, the chemical shift difference between the two oxygen nuclei has been found to be about 600 ppm,^{29–31} comparable to that found in ozone, consistent with previous analogies between FeO₂ bonding and that found in O₃.

6 SUMMARY AND PROSPECTS

Given the central importance of oxygen in biochemical systems (lipids, proteins, nucleic acids and carbohydrates), there have been remarkably few studies of ¹⁷O NMR chemical shifts, and even fewer studies aimed at detailed, quantum chemical analyses of chemical shifts and quadrupolar couplings. ¹⁷O NMR in biochemistry is therefore still in its infancy. However, with the advent of 750 MHz spectrometers, the current development of 900–1000 MHz machines, as well as recent development in quantum chemical applications to macromolecules,³⁵ ¹⁷O NMR can be expected to benefit enormously over the next few years. Thus, ¹⁷O chemical shifts and quadrupole couplings can be exploited to analyze, for example, lipid headgroup and backbone orientations in membranes, sterol orientations and interactions, peptide/protein structures in condensed phases, carbohydrate conformations and interactions, as well as small DNA structures. For ¹⁷O, only relatively low resolution magnets are required, thus the sensitivity gains possible with very high-field operation can be readily exploited. Indeed, most ¹⁷O NMR studies of biochemical systems reported to date could have been obtained at about 1 ppm resolution only. With recent improvements in computer price/performance ratios, and much more efficient algorithms, theoretical analyses of ¹⁷O shifts and χ values are also to be expected. Thus, ¹⁷O NMR in biochemistry undoubtedly has an extremely bright future.

1 INTRODUCTION

Natural products display remarkable structural diversity with many unusual bonding patterns and substituents commonly encountered. This structural variety makes general approaches to characterization challenging. NMR spectroscopy, with its extensive availability of pulse sequences, offers one of the best general solutions to these difficult structural problems and most molecular characterizations now include at least some NMR data. While relatively standard NMR approaches have developed, these techniques can, at times, allow for ambiguity in shift assignment, structure, conformation and stereochemistry. Fortunately, such NMR based characterizations continue to improve. The INADEQUATE experiment provides one of the best solutions for establishing bond connectivity but is seldom used because of intrinsic sensitivity problems. Herein an INADEQUATE approach is presented that relies on automated software analysis of data to greatly increase the sensitivity of the experiment and make more routine application feasible. Complementing the bond assembly information of INADEQUATE are conformational and stereochemical detail. While this information is typically obtained by solution NMR through proton-proton interactions, solid-state NMR offers access to more accurate characterizations. Therefore, recent investigations into the use of solid-state NMR shift tensors to extract such information are presented. Comparison to corresponding X-ray structures provides independent verification of these solid-state NMR approaches.

2 TRADITIONAL ROUTES TO STRUCTURE

Examination of the natural products literature reveals that NMR structural characterizations typically involve obtaining

a molecular formula by mass spectroscopy, 1D ^1H and ^{13}C analyses, and other experiments usually including DEPT or APT, COSY, HSQC, and HMBC. Most analysts recognize the potential for ambiguity inherent to these approaches and rely heavily on analogy to previous studies of related molecules. Use of the INADEQUATE NMR analysis is less frequently encountered with only about 80 natural product structures being reported at natural abundance since the introduction of the method by Bax et al. in 1980.¹ The primary difficulty with INADEQUATE is a lack of sensitivity. However, the INADEQUATE directly establishes carbon skeletons and thus offers more rigor than more commonly used NMR experiments. This is perhaps best illustrated by those INADEQUATE studies that have reexamined previously proposed structures. Despite the limited published use of this approach, numerous structural and shift assignment corrections have been made with nearly 20% of published INADEQUATE natural products reports consisting of such revisions. With an average of only four INADEQUATE studies being reported annually, the uncertainty in typical structural assignments may be higher than realized. This potential for structural errors using currently adopted techniques is generally unappreciated.

The primary source of error in more conventional experiments appears to lie in their strong reliance on the presence of protons and their coupling to other nuclei in the molecule. Molecules lacking protons within 3 bonds or roughly 5 Å of a given carbon are at risk of being misassigned. Hence, even a locally hydrogen depleted region potentially leads to ambiguity in structural determination. In addition, three bond couplings (both $^3J_{\text{HH}}$ and $^3J_{\text{HC}}$) are predicted by the Karplus relationship to have magnitudes near zero for dihedral angles near 90° and 270°.² Hence, such conformations are missing from H–H and H–C correlation experiments. Further complicating the problem is the assumption, often made, that couplings of only 2 and 3 bonds are detectable in experiments. This can be particularly serious in long range C–H coupling experiments such as the HMBC. Strong couplings through more than 3 bonds are known to occur and can have surprising structural origins. Since the H–C correlation experiments show signals for coupled pairs, but give no information regarding magnitudes of the coupling, long range couplings are unidentifiable as such and can complicate the assignment process. The INADEQUATE approach to structure greatly eliminates the risk of error inherent in typical NMR studies.

3 INADEQUATE STRUCTURAL DETERMINATIONS

INADEQUATE has long been recognized as a powerful experiment, but requires the presence of 2 adjacent ^{13}C s for detection.¹ At natural abundance, only 1 in approximately 10 000 carbon pairs satisfy this criterion and thus INADEQUATE is unusually insensitive. Typical expectations are that over a hundred milligrams of a moderate molecular weight molecule are needed for successful analysis. As most new natural materials are isolated in much smaller quantities, this experiment has largely been unavailable to natural product chemists. In the past decade Dunkel et al. have developed software for INADEQUATE data analysis that greatly increases sensitivity. A more complete description of this approach has been given elsewhere.³ This analysis technique has the advantage of examining all quadrature phase components of the

2 CHEMICAL APPLICATIONS

dataset eliminating the need for phasing. For low signal-to-noise datasets corresponding manual phasing is nearly impossible and can cause peaks to be missed as only the real-real component of the 2D spectrum is typically examined. The software models second order coupling effects, providing the ability to differentiate such signals from noise at low signal intensities. In practice this software has provided the

ability to characterize natural products using a little as 11 mg (30 μ moles) of material.⁴ Such datasets are nearly impossible to analyze manually as seen in the INADEQUATE spectrum of the obscurinervidine (Figure 1). However, a software evaluation of the obscurinervidine data identified most bonds with high statistical confidence.⁵ This greatly reduced demand for material makes it possible to apply the INADEQUATE on a

Figure 1 Comparison of the 2D INADEQUATE from the alkaloid, obscurinervidine, processed by standard techniques (top) and simulated from connections established by software analysis (bottom). Optimal phase parameters, determined by the computer analysis, were used to process the experimental data. The low signal-to-noise peaks observable in the upper right quadrant of the experimental spectrum are observable only after optimal phasing

more routine basis. The present version of the software fits anti-phase lineshapes in 2D INADEQUATE datasets. However, in principal, the software enhancements in sensitivity over manual analysis should also obtain for versions of the INADEQUATE displaying in-phase line shapes.⁶

Application of the INADEQUATE experiment is additionally complicated by the need to select an appropriate $^1J_{CC}$ value for use in the pulse delay, $[nJ_{CC}]^{-1}$, before the experiment begins. However, in natural products $^1J_{CC}$ values ranging from 35 to 80 Hz are common, making selection of a single correct value nearly impossible. While more recent versions of the pulse sequence are reasonably forgiving of this problem it remains a concern when the $^1J_{CC}$ values are inordinately different.⁷ Fortunately, in practice, it is observed that setting the $^1J_{CC}$ value to match the largest anticipated value in the molecule often allows detection of almost all carbons present.⁵ This apparently results from the strong dependence of the $^1J_{CC}$ value on carbon hybridization. Carbon-carbon bonds having small $^1J_{CC}$ values, typically sp^3-sp^3 bonds, involve carbons that carry more hydrogens and thus experience improved Overhauser enhancements. Since these signals are strongest, they can most afford to lose intensity because of a poor $^1J_{CC}$ selection and still remain detectable.

While carbon-carbon connectivity information from INADEQUATE is the primary goal, the $^1J_{CC}$ information obtained from the experiment is also of value. The $^1J_{CC}$ strongly reflects the % s character of a C-C bond (see Table 1) and thus can be important for identifying certain bonding arrangements.^{8,9} In our lab this has proven useful in identifying the presence of epoxides in new natural materials. For three membered rings, such as epoxides, the % s character in the 'bent bonds' is anticipated to be smaller than the 25% expected from an sp^3-sp^3 bond.¹⁰ Comparison of reported $^1J_{CC}$ values for a number of epoxides versus similarly substituted diols confirms this trend with $^1J_{CC}$ values of 30.1 ± 1.7 versus 41.5 ± 0.4 Hz observed, respectively.⁹ This difference allows confident INADEQUATE identification of epoxides through examination of the $^1J_{CC}$ of adjacent carbons having shifts consistent with oxygen substitution.

Inclusion of the computerized INADEQUATE analysis suggests a more rigorous path to structural characterization than is typically used. Such an approach includes mass spectral analysis and NMR experiments including DEPT, INADEQUATE, HSQC and HMBC. The mass spectral analysis provides a molecular formula. The DEPT and INADEQUATE identify the carbon type (i.e., CH_3 , CH_2 , CH or quaternary) and all C-C connectivities, but cannot establish connectivity through heteroatoms. The heteronuclear correlation experiments, HSQC and HMBC, provide this final information giving the structure. This suggested approach relies on heteronuclear correlation

experiments solely for establishing connections through heteroatoms and structures obtained are less prone to error. In addition, the suggested procedure directly and unambiguously determines the majority of an unknown structure, reducing the need for 'assignment by analogy'. However, structures determined by all of the procedures described still lack stereochemical and conformational information.

4 CONFORMATIONAL ANALYSIS USING SOLID-STATE NMR

Molecular conformation and stereochemistry are typically established by solution NMR or X-ray crystallography. NMR analyses usually rely on H-H interactions to establish either distances between protons through nuclear Overhauser enhancements or to find H-C-C-H dihedral angles through the $^3J_{HH}$ and the Karplus relationship.² Unfortunately, both methods are of limited use for hydrogen depleted substances. In such cases solid-state NMR offers a powerful alternative that is competitive even with X-ray when a hydrogen atom conformation is in question. The proposed approach involves comparing experimental shifts with ab initio computed values for model structures. Computed shifts can be obtained for any proposed conformation or stereochemistry by simply building the desired structure with a computer program, optimizing relevant geometry and calculating the corresponding shift tensors. A best fit of the experimental data to computed values establishes a best structure. Of particular interest is the use of chemical shift tensor principal values obtainable from solids from recently introduced techniques. In the work summarized here experimental principal values obtained either from the PHORMAT or FIREMAT techniques are employed.^{11,12} Using these techniques three principal tensor values are obtained per nucleus rather than the average of these values provided by the liquid isotropic shift. Furthermore, principal values represent electronic shielding in characteristic directions for a given nucleus, making the correlation of shift and structure more direct than corresponding studies involving the isotropic shift. However, this comparison assumes the ability to compute shift tensors that accurately reproduce measured quantities. Fortunately, computational methods have greatly improved in the past decade.

Several chemical shift tensor computation methods are now commercially available. However, before these methods can be employed for structural analysis the magnitude of the errors must be established. Initial error analyses emphasized only the isotropic shift.¹³ However, use of tensor values allows the origin of systematic computational errors to be more readily identified due to the association of specific tensor components with characteristic directions in a given moiety. A comparison was made for five methods (HF, BLYP, BPW91, B3LYP, and B3PW91) and 135 principal shift values obtained from caryophyllene oxide and parthenolide (Table 2).¹⁴⁻¹⁹ All included computational methods compute sp^2 carbon tensors with less accuracy than corresponding sp^3 values due to electron correlation. Hence, errors for sp^2 and sp^3 carbons were determined separately in parthenolide where sufficient carbons of each type were available. For the compounds examined, the B3PW91 method gave the best results and provided all computed shift values reported herein. The quality of fit is graphically displayed in Figure 2. The relatively small overall

Table 1 Typical $^1J_{CC}$ values for carbon-carbon bonds

Compound	Hybridization	Percent s-character	$^1J_{CC}$ value
CH_3-CH_3	sp^3-sp^3	25	34.6
$CH_3-CH=CH_2$	sp^3-sp^2	29	41.9
$CH_3-C\equiv CH$, $H_2C=C=CH_2$	sp^3-sp , sp^2-sp^2	33	67.4, 67.6
$H_2C=C=CH_2$	sp^2-sp	40	98.7
$HC\equiv CH$	$sp-sp$	50	171.5

Table 2 Comparison of tensor computational methods for caryophyllene oxide and parthenolide^a

	Caryophyllene oxide ^b	RMS error (ppm)	
		sp ²	sp ³
HF	5.6	4.9	2.5
BLYP	4.5	4.7	2.4
BPW91	3.7	4.4	2.2
B3LYP	3.5	3.7	2.2
B3PW91	3.1	3.5	2.0

^a Structures used for all calculations consisted of X-ray positions for heavy atoms and B3LYP/6-31G* refined hydrogen positions. The D95** basis set was used for all computed tensors.

^b Caryophyllene oxide contains only two sp² carbons and thus does not allow for separate error analyses of sp² and sp³ carbons.

Figure 2 Correlation plot of shift versus shielding for 135 principal values obtained from the terpenes parthenolide and caryophyllene oxide. All shielding values were computed using the B3PW91 method using the D95** basis. Respective slope and intercept values of 1.006 and 194.933 were found for sp² carbons (□) while values of 1.031 and 190.325 were computed for sp³ carbons (○)

error of 2.1 and 3.3 ppm for sp³ and sp² carbons, respectively, suggests that structural investigations using computed tensors are feasible.

The sensitivity of computed tensors to structure was demonstrated in practice by the measured tensors for parthenolide (Figure 3).¹⁹ Here, two geometrically distinct molecules are found in the crystallographic unit cell (i.e., two molecules per asymmetric unit). The two molecules are nearly identical (see Figure 4) differing by only 0.017 Å and 2.7° in bond lengths and dihedral angles, respectively, on average. However, the experimental isotropic spectrum differentiates the two molecules of the asymmetric unit with two lines observed for most molecular positions (Figure 5). Assignment of carbons to distinct molecules of the asymmetric unit is normally challenging as lines of a pair represent the same molecular position

Figure 3 Structure of parthenolide

Figure 4 The two molecules of parthenolide present in the crystallographic asymmetric unit superimposed to show their similarities. Corresponding bond lengths and dihedral angles differ by only 0.017 Å and 2.7°, respectively, on average. Computed tensor principal values are sufficiently accurate to allow assignment of 10 of the 15 carbons to a specific molecule of the asymmetric unit

with only minor differences present in the local environments. Despite these similarities, computed tensors are sufficiently accurate to allow ten of the fifteen pairs of carbons in parthenolide to be assigned to a specific molecule of the asymmetric unit with reasonable statistical confidence as summarized in Table 3.

The small relative errors in the computed tensors also allow shift assignments to molecular position to be made. Correct assignments are crucial, as the correlation of structure to tensor values requires a correct identification of molecular positions. In the work summarized here, preliminary assignments were made by comparison of solid-state isotropic shifts to INADEQUATE determined solution isotropic values. Since differences in shift are known to occur between liquids and solids, solution assignments are considered reliable only when no other peaks are within ± 10 ppm of a given line. The isotropic lines in the solid may then be differentiated by carbon type (i.e., CH₃, CH₂, CH, or quaternary) in a spectral editing procedure.²⁰ Remaining unassigned resonances within a given subgroup are then assigned by making all possible arrangements of computed tensors with experimental values. For each, an error is calculated and the best assignment identified. A statistical confidence in the assignment is provided by an F-test. This ability to confidently assign shifts and the demonstrated sensitivity of tensors to minor structural variation invites application to conformational analysis.

Figure 5 The isotropic spectrum of solid parthenolide showing the doubling of lines arising from minor geometric differences between the two molecules of the asymmetric unit. An asterisk denotes lines assigned to the same molecule of the asymmetric unit

Figure 6 Probability surface for the C_α of alanine in G*AV. The Z-surface shown includes contributions to the fit from the isotropic shift, the span ($\delta_{11}-\delta_{33}$), and $\delta_{22}-\delta_{11}$. The boxed region contains the area of highest probability and is expanded in the right-hand plot

Figure 7 Structure of verbenol

Initial investigation of the sensitivity of principal values to molecular conformation were performed by Pines et al. using tripeptides which were ^{13}C labeled at the α -carbon of the central amino acid.²¹ Comparisons of measured C_α principal values to corresponding ab initio computed values from conformationally varied model structures were performed using the Z-surface method, which gives the Bayesian probability

Figure 8 F-value versus dihedral angle for model conformations of verbenol. Tensors were computed at 30° intervals in the hydroxy dihedral angle (C3-C4-O-H) with extrapolated values used for intermediate angles. The 90% statistical confidence level is shown. Each curve shown corresponds to one of the three molecules of the asymmetric unit

that a given conformation (i.e., an ϕ/ψ pair) corresponds to experimental principal values.²² The NMR analysis accurately predicted the X-ray determined conformation within $\pm 12^\circ$ (Figure 6), validating the proposed approach. Further theoretical work by Oldfield et al. has demonstrated that the C_α principal values are especially sensitive to backbone conformation in several amino acids.²³ More recently, the introduction of improved experimental methods has eliminated the need to isotopically label materials and allows extensions of the methodology to less easily labeled materials like natural products.

Table 3 Principal values for parthenolide and corresponding theoretical values

^a Theoretical tensor values, given in parentheses, calculated using the B3PW91 method and 6-31+G (2d, p) basis. Structure used consisted of X-ray positions for heavy atoms and B3LYP/6-31G** refined hydrogen positions.

^b Isotropic experimental shifts obtained from a separate CP/MAS experiment. Theoretical isotropic values computed from the average of calculated principal values.

^c Solution values obtained from 2D INADEQUATE.

^d Principal values for these carbons were obtained from a FIREMAT analysis. All other values are derived from PHORMAT data.

The terpene verbenol (Figure 7) provides an ideal model to test the sensitivity of tensors to conformation in natural products.²⁴ Here the bicyclic ring system eliminates conformational flexibility from the majority of the molecule, with significant flexibility remaining only in the orientation of the hydroxy hydrogen. Relative orientation of the methyl groups is not considered as it is assumed that local steric factors accurately locate them. However, location of the hydroxy hydrogen often reflects lattice effects, making the characterization of orientation in isolated molecules difficult. To test the sensitivity of tensors to molecular conformation, twelve models were prepared in which the hydroxy hydrogen was rotated about the C–O axis in 30° increments. At each point the C–C–O–H dihedral angle was fixed and the remaining structure optimized via an energy minimization procedure. Computed tensors that displayed variation in tensors versus conformation larger than the anticipated error were used to characterize the best conformation. X-ray analysis of verbenol indicates that there are three molecules per asymmetric unit.²⁵ Hence up to three lines per

carbon are observed in the isotropic spectrum. Comparison of computed tensors with experiment for all angles by an F-test provided a best fit at roughly 60° ± 15° for each of the 3 distinct molecules of verbenol (Figure 8). This predicted conformation compares favorably with the X-ray determined angles of 55°, 69°, and 74°, validating the approach chosen.

5 STEREOCHEMICAL DETERMINATION USING SOLID-STATE NMR

The sensitivity of molecular conformation to tensors suggests that stereochemistry may also be predicted by principal values. Determination of stereochemistry in new natural products is an important and frequently encountered step. Characterization by solid-state NMR offers a solution in cases where X-ray or solution NMR fail as previously discussed. A comparison of experimental principal values with *ab initio* computed values for all possible diastereomers, analogous to

Figure 9 Structure of terrein

the approach proposed for conformational analysis, provides a solution.

The natural product, terrein, (Figure 9) has a relatively simple structure and the presence of only two stereocenters making

it an ideal compound for investigating the sensitivity of tensors to stereochemistry. While absolute stereochemistry is unavailable from tensor data, principal values may potentially establish relative stereochemistry. Hence an analysis of terrein in which experimental principal values are compared with *ab initio* computed tensors for the 2R, 3S and 2S, 3S diastereomers is sufficient to establish relative stereochemistry.²⁶ Principal values cannot differentiate enantiomers, hence, comparisons involving any of the other three possible diastereomeric pairs (i.e., 2R, 3S and 2R, 3R or 2S, 3R and 2R, 3R or 2S, 3R and 2S, 3S) are equivalent as they involve only the exchange of one enantiomer for another and thus offer no additional information.

Conformational flexibility complicates the stereochemical analysis and must necessarily be included in the analysis. In terrein, a variety of conformations differing only in orientation of the hydroxy hydrogens at C2 and C3 were prepared for each diastereomer. Each conformation was then subjected to

Figure 10 Probability surfaces illustrating the superior fit of the 2R, 3S stereoisomer (plot A) to the experimental data. In contrast, the 2S, 3S diastereomer (plot C) is a poor fit to experiment regardless of the chosen conformations. The 2R, 3S diastereomer can be differentiated from the best-matched 2S, 3S diastereomer with a high statistical probability of >99.5%. Plot B shows an alternative processing of the data from that in A. This Z-surface provides a more visually distinguishable local maxima for peaks of high probability but suppresses three marginally less probable peaks as denoted by the asterisks in plot D. The contour plot D lends statistical meaning to plots A and B by showing the 80% and 90% probability levels. The vertical scales in plots A and C are identical to allow direct comparison and represent the inverse F-value

a constrained geometry optimization and tensors computed. Tensor information from the stereocenters at carbons 2 and 3 are anticipated to provide the most sensitive information and initially are the only carbons included in the analysis.

Computed tensors for the two diastereomers of terrein differ significantly, allowing a confident assignment (>99.5% probability) of the stereochemistry as 2R*, 3S*. This is shown in a plot of probability versus hydroxy dihedral angles for the 2R, 3S and 2S, 3S diastereomers in Figure 10(A) and 10(C), respectively. Figure 10(B) shows the data from plot 10A processed using Oldfield's Z-surface technique for comparison to work shown in Figure 6.²² Z-surfaces give more pleasing visual portrayal of areas of conformational best fit when compared to the corresponding surface of inverse F-values shown in the left-hand plots. However, Z-surfaces exponentially suppress peaks from marginally less probable conformations as seen in plot 10D where the 80% and 90% probability levels equally appropriate for both plots 10A and 10D are shown. The visually distinct peaks in the Z-surface are seen to correspond to roughly the 80% probability level. However, three additional regions are within 10% of the 80% probability level, as denoted by asterisks in plot 10D, but are completely unrecognized in the Z-surface of plot 10B. The conformations predicted in Figure 10 are from a limited sampling of the surface. More accurate predictions were obtained by greater sampling near regions of high probability.

Inclusion of additional data points near local maxima ($\text{H-O-C2-C1} = 50^\circ$ and $\text{H-O-C3-C2} = 70^\circ$) provides most probable molecular conformations with an associated statistical significance. In terrein the region of conformational best fit for the hydroxy hydrogens corresponds with the X-ray determined orientations (see Figure 11).²⁷ The error in the NMR predicted H-O-C2-C1 angle was roughly the same ($\pm 20^\circ$) as that observed in the analysis of verbenol (top plot of Figure 11). However the error in the H-O-C3-C2 angle was nearly three times as large, suggesting a deficiency in the theoretical model or the presence of temporal fluctuations in the structure that is neglected in the shift model. Inclusion of conformational disorder in the model, performed by averaging tensor values for two different model conformations, resulted in a significant improvement in predicted conformation (see bottom plot of Figure 11). Final predicted conformations of $52^\circ \pm 12^\circ$ and $58^\circ \pm 11^\circ$ in the H-O-C2-C1 and H-O-C3-C2 angles, respectively, were made using the disordered model. Corresponding X-ray positions are 68° and 60° , supporting the NMR approach.

A corresponding prediction of stereochemistry and molecular conformation can be performed using only isotropic shift values. Isotropic shifts lack the directional information of the principal values but are more easily obtained. In terrein, a comparison of computed and experimental isotropic shifts correctly identifies the stereochemistry as 2R*, 3S*, but at a significantly reduced confidence (roughly 80% probability level compared to >99.5% from tensor shifts). Molecular conformations are likewise determined with much less confidence with nearly 80% of the potential conformations statistically indistinguishable from one another. Principal values thus appear to offer a superior assessment of both stereochemistry and molecular conformation than corresponding isotropic values.

Figure 11 Contour maps showing selection of high probability dihedral angles in 2R, 3S terrein when additional data points near local maxima ($\text{H-O-C2-C1} = 35^\circ\text{--}70^\circ$, $\text{H-O-C3-C2} = 10^\circ\text{--}130^\circ$) are included. The top plot ignores motional disorder and displays contours at the 80% and 90% probability levels. In the lower plot, the effect of conformational disorder in the H-O-C2-C1 and H-O-C3-C2 angles is shown. Conformational averaging by $\pm 20^\circ$ and $\pm 60^\circ$, respectively, about any given point were performed. The lower figure includes contours at one standard deviation and the 80% probability levels. The H-O-C2-C1 angle is defined such that 0° denotes the O-H eclipsing the C1-C2 bond with subsequent increases in angle indicating rotation towards the C2-H bond. The H-O-C3-C2 angle is likewise defined with the O-H eclipsing the C2-C3 bond at 0° and positive increments of angle denoting rotation towards the C3-C4 bond. The X-ray determined conformation is indicated with an X

6 CONCLUSIONS

Structural determination in natural products may be improved by a more routine use of the INADEQUATE experiment. Prior sensitivity concerns have been addressed by the introduction of a computer analysis technique coupled with improvements in available pulse sequences. In cases

where stereochemistry and molecular conformation are also of interest, solid-state NMR offers an alternative route to this information. The NMR approach complements presently available methodologies and appears to be especially useful for non-crystalline or hydrogen depleted materials. Presently, the proposed methods clearly characterize the stereochemistry and provide molecular conformations with reasonable errors. Assessment of conformational errors is presently limited by comparable errors in the corresponding X-ray determined hydrogen positions. Future extensions of the conformational analysis to systems involving non-hydrogen atoms should provide more accurate comparisons with X-ray values and thus establish the reliability of the NMR approach.

1 INTRODUCTION

The story of how Nature synthesizes the corrin structure of vitamin B₁₂ began about 4×10^9 years ago, when archaeobacteria first grew on our planet in an anaerobic atmosphere. (The subject has been reviewed by Scott, by Battersby, and by Leeper.¹) Largely through the power of NMR spectroscopy, in combination with molecular biology and enzymology, the last 25 years have witnessed the elucidation of the pathway to hydrogenobyirinic acid (Scheme 1), which serves as the precursor to the vitamin via side-chain amidation, cobalt insertion, and addition of the nucleotide loop.

In 1968, at Yale, armed with a home-made FT NMR spectrometer, and liters of *Propionibacterium shermanii* cells, we were able to obtain 2–5% incorporations of the ¹³C-enriched substrates aminolevulinic acid (ALA), porphobilinogen (PBG), and, most importantly, uro'gen III (Scheme 1) to observe ¹³C signals above natural abundance (1.1%) in vitamin B₁₂, thus linking the porphyrin and corrin pathways. Later, with L. Siegel (Duke) and G. Müller (Stuttgart), we found and identified the structure of the intermediates precorrins-2 and -3 in their oxidized forms,¹ although the spectroscopy involved 11 days of continuous acquisition of ¹³C at natural abundance. After this initial burst of success, the next decade was spent in the search for further intermediates during which a great deal was learned about enzymes 2, 3, and 4 (Scheme 1), but, apart from finding the sequence of C-methylation by ¹³CH₃-S-adenosyl methionine (SAM) in a 'pulsed' ¹³C/¹²C time course, the steps between precorrin-3 and the corrin structure remained cryptic until 1987, when Roth showed that *Salmonella typhimurium* makes B₁₂ anaerobically, and provided the necessary plasmids and the DNA sequences of the corrin operon—the *cbi* genes—for overexpression in *E. coli*.¹

The corresponding *cob* genes of *Pseudomonas denitrificans* (Rhône-Poulenc, Paris) now became accessible,² so that, by mid-1990, the complete repertoire of corrin-synthesizing enzymes for both the anaerobic and aerobic pathways was in hand. Now came the fascinating problem of matching each gene product to its function. Collaborative work in Paris and Cambridge¹ (A. R. Battersby) had established the pathway from precorrin-6x to the cobalt-free corrin, hydrogenobyirinic acid (see Scheme 1). Our strategy for deducing the function of the enzymes connecting precorrin-2 and -6x was to enrich precorrin-2 biosynthetically with ¹³C, then watch the growth of new signals in the NMR spectrum when incubated with

each of the gene products in turn, in the presence of ¹³CH₃-SAM. Space does not permit other than a brief summary of this complex pathway, but the following examples taken from our own work covering the central section of Scheme 1 typify the NMR techniques used.

2 THE FIRST METHYLTRANSFERASES, THEIR SPECIFICITIES, AND THE SYNTHESIS OF PRECORRIN-2

Uro'gen III (enriched from [5-¹³C]ALA at the positions (■) shown in Scheme 2) was prepared by mixing the enzymes 1, 2, and 3 (dehydratase, deaminase, and uro'gen III synthase) and then incubating with the first methyltransferase, M-1 (enzyme 4), and [¹³CH₃]SAM. The resultant spectrum of precorrin-2 revealed only one sp³ enriched carbon (■) assigned to C-15, thereby locating the reduced center. By using a different set of ¹³C labels (● from [¹³C-3]ALA) and [¹³CH₃]SAM the sp² carbons at C-12 and C-18 were located as well as the sp³ centers coupled to the pendant ¹³C-methyl groups at (*) C-2 and C-7. This result³ confirms an earlier NMR analysis⁴ of precorrin-2 isolated by careful anaerobic purification of the methyl ester, and shows that no further tautomerism takes place during the latter procedure. The two sets of experiments mutually reinforce the postulate that precorrins-1, -2, and -3 all exist as hexahydroporphinoids, and recent labeling experiments⁵ have provided good evidence that precorrin-1 is discharged from the methylating enzyme (SUMT) as the species with the structure shown in Scheme 1.

However, prolonged incubation (2 h) of uro'gen III with M-1 provided a surprising result, for the UV and NMR changed dramatically from that of precorrin-2 (a dipyrrocorphin) to the chromophore of a pyrrocorphin, hitherto known only as a synthetic tautomer of hexahydroporphyrin. At first sight, this event seemed to signal a further tautomerism of a dipyrrocorphin to a pyrrocorphin catalyzed by the enzyme, but when ¹³CH₃-SAM was added to the incubation, it was found that a *third* methyl group signal appeared in the 19–21 ppm region of the NMR spectrum. When uro'gen III was provided with appropriate ¹³C labels (●) (Scheme 2), three pairs of doublets appeared in the sp³ region ($\delta = 50\text{--}55$ ppm) of the pyrrocorphin product. The necessary pulse labeling experiments together with appropriate FAB MS data finally led to the structural proposal (Scheme 2)⁶ for the novel trimethylpyrrocorphin produced by 'overmethylation' of the normal substrate, uro'gen III, in the presence of high concentration of enzyme. Thus, M-1 has been recruited to insert a ring C methyl and synthesize the long-sought 'natural' chromophore corresponding to that of the postulated precorrin-4, although in this case the regiospecificity is altered from ring D to ring C. Under physiological conditions, however, the next step catalyzed by enzyme 5 (M-2; Scheme 1) inserts the next SAM-derived methyl group at C-20 to reach precorrin-3.

3 FROM PRECORRIN-3 TO HYDROGENOBYIRINIC ACID

Using ¹³C NMR spectroscopy as a probe for the activity of all the overexpressed enzymes of the B₁₂ pathway

2 VITAMIN B₁₂

Scheme 1

Scheme 2

in *P. denitrificans* each enzyme in turn was tested with precorrin-3 as substrate, and it was found that CobG⁷ serves as an O₂-dependent enzyme whose role is to install oxygen-derived functionality at C-20, thus preparing the macrocycle for ring contraction. Remarkably, the resultant spring-loaded mechanism *does not operate until after the fourth C-methylation has occurred at C-17*, an event that is mediated by CobJ,⁷ a SAM-requiring enzyme, thereby defining both the ring contraction and C-17 methylation sequences.

The NMR assays for the activities of CobG and J were developed as follows. First, precorrin-3 was prepared in two ¹³C-isotopomeric versions—A, from [¹³C-4](●)-, and B, from [¹³C-5](■)-5-aminolevulinic acid, using the multienzyme synthesis described earlier,⁸ as shown in Scheme 3. The reaction of isotopomer A (●) with CobG in the presence of O₂ and NADH resulted in a spectrum almost identical with that of the substrate except for the disappearance of the signal (●) for C-1 at δ = 146 ppm and the appearance of a peak (●) at δ = 106 ppm corresponding to sp³ geometry and a new environment at C-1. When isotopomer B (■) served as substrate, the pattern of NMR signals remained constant, except for the resonance for C-20 (at δ = 103 ppm), which was replaced by a signal at δ = 78 ppm corresponding to oxygen insertion and resultant sp³ hybridization at this center. In a separate experiment using precorrin-3 enriched at the C-20 methyl, the CH₃ signal (*) at C-20 (δ = 17.6 ppm) in precorrin-3 underwent a high-frequency shift to δ = 25 ppm during incubation with CobG. The above spectral changes are in accord with the addition of oxygen at both positions 1 and 20, and together with the observation by infrared spectroscopy

of a γ-lactone (1799 cm⁻¹), lead to the structural proposal for the new product, precorrin-3x (Scheme 3), whose formation can be rationalized by epoxidation at C-1,20 by the O₂-dependent CobG enzyme, followed by participation of the ring A carboxylate in a lactonization-ring opening sequence. In the absence of O₂, no reaction of precorrin-3 with CobG was observed.⁹

Next, addition of SAM and, in turn, each of the remaining putative methyl transferases in the *P. denitrificans* repertoire (CobF, J, M) to precorrin-3x labeled from [4-¹³C]ALA (●) resulted in a new signal for C-17 (δ = 66 ppm) corresponding to C-methylation at this center, *only when CobJ was present*. Confirmation that C-17 is indeed the site of the fourth methyl insertion came from double labeled incubation of isotopomer A (●) and ¹³CH₃-SAM (*) in the presence of *both* CobG and J. In this experiment, the new CH₃ signal (*) appearing at δ = 22.5 ppm was coupled (*J* = 37 Hz) to the C-17 resonance (●; δ = 66 ppm) (Scheme 3). Most significantly, the ¹³C NMR spectrum of the new precorrin-4 also displays a pair of coupled carbons C-1, C-19 (δ = 82, 142 ppm, *J* = 52 Hz), showing that ring contraction occurs during incubation with CobJ. When the two-enzyme incubation was repeated using isotopomer B (■), the signal for C-20 in the product appeared at δ = 210 ppm, indicating that ring contraction is accompanied by the genesis of a new methyl ketone function pendant from C-1, by a process that corresponds formally to the pinacol-type rearrangement illustrated in Scheme 3. Analysis of the full set of spectral data (NMR, FAB MS, and FT IR) leaves no doubt that the new isolate is precorrin-4,^{7,10} the long-sought tetramethylated intermediate of corrin biosynthesis.

Scheme 3

It is of considerable interest for the evolution of vitamin B₁₂ synthesis that Nature should use both a 'modern' aerobic pathway (i.e., less than 2×10^9 years old) involving metal-free substrates for most of the way (Scheme 1), as well as the ancient, anaerobic sequence (dating to about 3.8×10^9 years) in which cobalt is inserted very early,¹¹ implying a corresponding dichotomy of the mechanism of ring contraction, in which O₂ is replaced in the metallo system by a two-electron valency change. Thus, the cobalt complex of precorrin-3x could be reached in the *Salmonella typhimurium* and *P. shermanii* series via internal redox of Co(III) → Co(I), which is formally equivalent to a two-electron oxidation of the ligand.

The discovery of the ring contractase system (CobG and CobJ) and the fourth methylating enzyme for C-17 (CobJ) (Scheme 3) reveals the way in which aerobic corrin biosynthesis uses an early oxidative ring contraction step concomitant with C-17 methylation on the β (upper) face of the substrate, precorrin-3x, leaving only the enzymes mediating the fifth (C-11) and sixth (C-1) C-methylation steps to be found. These have been identified recently¹² as CobM, which produces another new intermediate, precorrin-5 (step 8 in Scheme 1), and CobF (step 9), respectively. CobF was found to be the C-1 methyl transferase catalyzing both the insertion of the sixth methyl group in precorrin-5 and deacetylation at C-1 to reach precorrin-6x. The route from precorrin-6x to (cobalt-free) hydrogenobyric acid (Scheme 1) has recently been described at the enzyme level,¹³ so that almost every intermediate in the aerobic pathway has now been identified by NMR spectroscopy, and all of the functions necessary for corrin biosynthesis assigned in *P. denitrificans*. There now remains the experimentally challenging problem of analyzing the parallel, yet distinct, pathway in *S. typhimurium* and *P. shermanii*, for in these organisms the gene products are handling substrates in the form of cobalt complexes whose valency changes are believed to be at the heart of the mechanism of ring contraction in these anaerobic bacteria.¹¹

It took an enormous international effort by Shemin, Scott (USA), Bykhovsky (Russia), Müller (Germany), Battersby (UK), and Arigoni (Switzerland) nearly 20 years to build the 'library' of the first seven intermediates,¹ yet, thanks to recombinant DNA technology, the remaining six structures (Scheme 1) have been discovered in the last three years—all of them determined by biosynthetic enrichment from ¹³C-ALA and ¹³CH₃-SAM.

1 INTRODUCTION

In principle, accurate interatomic distances can be evaluated from careful analysis of specific dipolar interactions that were normally sacrificed under the condition of high power decoupling and magic angle spinning (MAS) techniques. A number of methods to recouple a single pair of dipolar interaction among homo and hetero nuclear spin pairs under the magic angle spinning condition have been proposed for determining the interatomic distances.^{1–10} These distances have been used as constraints to determine the three-dimensional (3D) structure of peptides and proteins.^{11–16} Rotational Echo Double Resonance (REDOR) was explored to recouple the relatively weak heteronuclear dipolar interactions under the MAS condition by applying a π pulse synchronously with the rotor period.^{8,9} Consequently, the transverse magnetization cannot be refocused completely at the end of the rotor cycle, leading to a reduction of the echo amplitude. The extent of the reduction of the echo amplitude as a function of the number of rotor periods depends on the strength of the heteronuclear dipolar interaction. This method is extensively used to determine the relatively remote interatomic distance of 2–8 Å. When a number of isolated pairs are involved in a REDOR dephasing,

the REDOR transformation could be useful in determining interatomic distances because it yields single peaks against distance axis for each heteronuclear coupling strength.^{17,18} This approach is, however, not applicable for the case where the observed nuclei in REDOR are coupled with multiple nuclei.

It turned out that determination of accurate interatomic distances (± 0.1 Å) is a prerequisite to arrive at a unique 3D structure of peptides and proteins.^{15,16} It is emphasized that the distance measurement by REDOR is the only available means to satisfy this condition among the many kinds of proposed procedures mentioned above in view of the achieved accuracy and precision. Nevertheless, it is important to bear in mind that every possible effort to achieve the distance measurement with ultimate accuracy is essential to any possible applications. This is because any measurement based on the peak-intensity is susceptible to unexpected errors, which are not easy to check. After brief survey, tips to avoid this problem will be discussed in detail.

2 THEORETICAL BACKGROUND OF THE REDOR EXPERIMENT⁸

Transverse magnetization that precesses about the static magnetic field due to the dipolar interaction under the MAS condition moves back to the same direction at every rotor period because the integration of ω_D over one rotor period is zero. Consequently, the rotational echo signals are refocused at every rotor period. When a π pulse is applied to the I nucleus (Figure 1), which is coupled with the S nucleus, in one rotor period, this pulse plays a role to invert the precession direction of the magnetization of the observed S nucleus. Consequently, the magnetization vector of the S nucleus cannot move back to the same direction after one rotor period. Therefore the amplitude of the echo intensity decreases.

The extent of the reduction of the rotational echo amplitude yields the interatomic distances. To evaluate the REDOR echo amplitude theoretically, one has to consider the average precession frequency in the presence of the π pulse at the center of the rotor period over one rotor cycle as follows:

$$\begin{aligned} \overline{\omega_D(\alpha, \beta)} &= \pm \frac{1}{\text{Tr}} \left[\int_0^{\text{Tr}/2} \omega_D dt - \int_{\text{Tr}/2}^{\text{Tr}} \omega_D dt \right] \\ &= \pm \frac{D}{\pi} \sqrt{2} \sin 2\beta \sin \alpha \end{aligned} \quad (1)$$

Figure 1 Pulse sequence and timing chart of REDOR experiment

2 NUCLEAR INTERACTIONS

where α is the azimuthal angle and β is the polar angle defined by the internuclear vector with respect to the rotor axis. Therefore, the phase angle, $\Delta\Phi(\alpha, \beta)$ for the Nc rotor cycle can be given by

$$\Delta\Phi(\alpha, \beta) = \overline{\omega_D(\alpha, \beta)} NcTr \quad (2)$$

where Tr is the rotor period. Finally, the echo amplitude can be obtained by averaging over every orientations as follows

$$S_f = \frac{1}{4\pi} \int_{\alpha} \int_{\beta} \cos[\Delta\Phi(\alpha, \beta)] d\alpha \sin\beta d\beta \quad (3)$$

Therefore, the normalized echo difference, $\Delta S/S_0$, can be given by

$$\frac{\Delta S}{S_0} = \frac{S_0 - S_f}{S_0} = 1 - S_f \quad (4)$$

Experimentally, REDOR and full echo spectra are acquired for a variety of NcTr values and the respective REDOR (S_f) and full echo (S_0) amplitudes are evaluated.

3 ROTATIONAL ECHO AMPLITUDE CALCULATED BY THE DENSITY OPERATOR APPROACH¹⁵

The REDOR echo amplitude can be evaluated more rigorously by using density matrix operators and for the REDOR experiment. The time evolution of density operator, ρ_0 , under the heteronuclear dipolar interaction during one rotor period, can be considered by taking the pulse length into account. The average Hamiltonian in the rotating frame over one rotor period can be given by

$$\begin{aligned} \overline{\mathcal{H}} &= \frac{1}{Tr} \left[\overline{\mathcal{H}_1(t)\tau} + \overline{\mathcal{H}_2(t)\tau} + \overline{\mathcal{H}_3(t)\tau} \right] \\ &= \frac{D}{4\pi} \left\{ \sin^2\beta [\sin(2\alpha + \omega_r t_w) + \sin(2\alpha - \omega_r t_w) - 2\sin 2\alpha] \right. \\ &\quad - 2\sqrt{2}\sin 2\beta \left[\sin\left(\alpha + \frac{1}{2}\omega_r t_w\right) + \sin\left(\alpha - \frac{1}{2}\omega_r t_w\right) + 2\sin 2\alpha \right] \\ &\quad - \sin^2\beta [\sin(2\alpha + \omega_r t_w) + \sin(2\alpha - \omega_r t_w)] \frac{4\omega_r^2 t_w^2}{4\omega_r^2 t_w^2 - \pi^2} \\ &\quad + \sqrt{2}\sin 2\beta \left[\sin\left(\alpha + \frac{1}{2}\omega_r t_w\right) + \sin\left(\alpha - \frac{1}{2}\omega_r t_w\right) \right] \\ &\quad \times \frac{2\omega_r^2 t_w^2}{\omega_r^2 t_w^2 - \pi^2} \left. \right\} \hat{I}_Z \hat{S}_Z \\ &+ \frac{D}{4\pi} \left\{ \sin^2\beta [\cos(2\alpha + \omega_r t_w) + \cos(2\alpha - \omega_r t_w)] \right. \\ &\quad \times \frac{2\pi\omega_r t_w}{4\omega_r^2 t_w^2 - \pi^2} \\ &\quad - \sqrt{2}\sin 2\beta \left[\cos\left(\alpha + \frac{1}{2}\omega_r t_w\right) + \cos\left(\alpha - \frac{1}{2}\omega_r t_w\right) \right] \\ &\quad \times \frac{2\pi\omega_r t_w}{\omega_r^2 t_w^2 - \pi^2} \left. \right\} \hat{I}_Z \hat{S}_Y \\ &= a\hat{I}_Z \hat{S}_Z + b\hat{I}_Z \hat{S}_Y \end{aligned} \quad (5)$$

where ω_r is the angular velocity of the rotor and t_w is the duration of π pulse. $\overline{\mathcal{H}_1(t)}$, $\overline{\mathcal{H}_2(t)}$, and $\overline{\mathcal{H}_3(t)}$ are the average Hamiltonians corresponding to the period shown in Figure 1. Pulse length, t_w , is also considered in the calculations for the analysis of the REDOR results. The density operator, ρ (Tr), at Tr after evolution under the average Hamiltonian can be calculated as

$$\rho(Tr) = \exp(-i\overline{\mathcal{H}}Tr)\rho_0\exp(i\overline{\mathcal{H}}Tr) \quad (6)$$

where ρ_0 is considered to be $\hat{I}_Y$ after the contact pulse. Then finally the transverse magnetization at Tr can be given by

$$\begin{aligned} \langle \hat{I}_Y(Tr) \rangle &= Tr\{\rho(Tr)\hat{I}_Y\} \\ &= \cos\left(\frac{1}{2}\sqrt{a^2 + b^2}Tr\right) \end{aligned} \quad (7)$$

Echo amplitude in the powder sample can be calculated by averaging over every orientation as follows

$$S_f = \frac{1}{4\pi} \int_{\alpha} \int_{\beta} \langle \hat{I}_Y(Tr) \rangle \sin\beta d\beta d\alpha \quad (8)$$

Therefore, the normalized echo difference, $\Delta S/S_0$, can be given by equation (4). When the length of t_w is zero, equation (7) can be simplified as follows:

$$\langle \hat{I}_Y(Tr) \rangle = \cos\left(\frac{D}{\pi}\sqrt{2}\sin 2\beta \sin \alpha Tr\right) \quad (9)$$

In this case, equation (8) is equivalent to equation (3) in the case of Nc = 1.

4 SEPARATION OF S-I DISTANCES FROM A S_m-I_n MULTIPLE SPIN SYSTEM

It should be taken into account that a spin system for a doubly labeled sample should be generally treated as a multiple spin system ($S-I_n$ system) as shown in Figure 2(a) in which S^* is the observed nuclei and the recoupling pulse is applied to the I^* nuclei. The ideal S-I system is available only when the doubly labeled preparation is infinitely diluted with unlabeled preparation. In contrast, uniformly and singly labeled preparations are treated as S_m-I_n and $S-I_n$ systems, respectively (Figure 2b,c), although S^* in the latter is S nuclei of natural abundance. For this reason, it is advisable to utilize a variety of isotopically doubly labeled samples in order to obtain respective interatomic distances, although it is too laborious to make so many kinds of preparations. In fact, we made six kinds of doubly labeled preparations to determine the 3D structure of the pentapeptide, Leu-enkephalin.¹⁶ In addition, it is essential to make certain that all such preparations take the same polymorphic structure, because crystalline peptides or proteins under consideration may take different kinds of polymorphs depending on condition for crystallization, pH, temperature, etc.^{15,16} The most convenient way to check this problem is to use the conformation-dependent ¹³C chemical shifts,

Figure 2 Schematic representation of multiple spin systems for (a) doubly labeled, (b) uniformly labeled and (c) singly labeled samples

which are very sensitive to the presence of such polymorphic structure.^{15,16,19}

In this connection, use of a uniformly labeled sample seems to be more attractive both for the sample preparation and also to avoid the problem of polymorphs.²⁰ This view turned out to be not always true, however, because separation of a particular $S-I$ interaction from S_m-I_n spin systems, consisting of many homo- and heteronuclear dipolar and scalar interactions, is not always as straightforward as anticipated. In practice, all of the following conditions should be taken into account to determine the accurate interatomic distances of a particular spin pair from the uniformly labeled samples. First, J coupling among the observed S nuclei should be removed to reduce the phase twist due to the coherent evolution by J coupling, when its magnitude is comparable to the dipolar coupling, as illustrated for uniformly [^{15}N , ^{13}C]-labeled ammonium L-glutamate monohydrate at $\text{NcTr} = 8$ ms (Figure 3).^{21,28} This phase twist can be removed by using a shaped pulse as a Z-filter instead of a π pulse at the center position of the REDOR evolution period.²¹ Second, the linewidths of individual signals might be broadened due to strong homonuclear dipolar interaction with neighboring S nuclei, which should be eliminated by homonuclear decoupling pulses.²² Thus, in the case of a uniformly labeled sample, combination of both homonuclear dipolar and scalar decoupling is required to simplify the S_m-I_n to $S-I_n$ spin system. Third, relatively shortened transverse relaxation times (T_2), due to residual dipolar interactions, reduce the

Figure 3 ^{13}C -REDOR and full echo spectra at $\text{NcTr} = 8$ ms for crystalline uniformly labeled ammonium [^{15}N]-L-glutamate monohydrate

transverse magnetization during the dipolar recoupling period in REDOR experiments. This makes it difficult to observe the REDOR effect for the nuclei with relatively long internuclear distances, because it is required to measure relatively long evolution times to observe slow dephasing of the REDOR signals. Fourth, REDOR factors against the dipolar evolution time should be analyzed using multiply coupled $S-I_n$ spin systems rather than an isolated two-spin system under the condition of homonuclear decoupling.^{23–26} Accordingly, the four kinds of obstacles mentioned above should be removed to determine a set of accurate interatomic distances simultaneously for a uniformly labeled sample.

Gullion et al.²⁷ proposed a θ -REDOR as an approach to determine the individual interatomic distance in a uniformly labeled sample by dividing $S-I_n$ spin system into ' n ' number of isolated $S-I$ two-spin systems. This makes the REDOR analysis simple and allows one to use the REDOR transformation to obtain the dipolar coupling frequencies of individual $S-I$ spin couplings, although this method is not always easy to apply for measurement of a relatively long interatomic distance. Alternatively, homonuclear and scalar interactions are completely removed when natural abundant ^{13}C REDOR experiments were performed.²⁸ This approach provides an excellent means to determine the interatomic distances for a number of isolated spin pairs simultaneously under condition of high resolution (Figure 2c). Further, it is emphasized that this approach is free from the problem of the above-mentioned shortened T_2 values due to homonuclear ^{13}C spin interactions. However, a multiple coupled spin system, $^{13}\text{C}-^{15}\text{N}_n$, has still to be explicitly considered, because the intermolecular dipolar interactions cannot be neglected for a small molecule. In practice, we have recently demonstrated that accurate interatomic distances can be determined by analyzing intramolecular and

intermolecular dipolar contributions based on root mean square deviation (RMSD) between the theoretically and experimentally obtained REDOR factors.²⁸

5 TIPS FOR OBTAINING ACCURATE INTERATOMIC DISTANCES BY REDOR EXPERIMENT

It is emphasized that determination of interatomic distances accurate to 0.1 Å is a prerequisite to arrive at a unique solution of the three-dimensional structure of peptides, proteins, etc. A careful evaluation of the following points are the most important steps to obtain reliable interatomic distances by the REDOR experiment, although they have not always been seriously taken into account in a number of papers so far published.

5.1 The Finite Pulse Length and Fluctuation of RF Power

This effect is experimentally observed and calculated using equation (8) as shown in Figure 4. The REDOR parameter, $\Delta S/S_0$, as measured for 20% [1-¹³C, ¹⁵N]Gly($r_{\text{CN}} = 2.48$ Å) is plotted for the lengths of the ¹⁵N π pulse of 13.0 μs for the experiment and 24.6 μs (chosen to satisfy 10% rotor cycle) as a function of NcTr with the calculated lines using the π pulse

Figure 4 ¹³C REDOR and full echo spectra of [1-¹³C, ¹⁵N]glycine as recorded by the rotor frequency of 4000 Hz and NcTr of 4 ms (a) and plots of the $\Delta S/S_0$ vs. NcTr (b). Solid and open circles denote the experimental points recorded using a ¹⁵N π -pulse of 13.0 and 24.6 μs , respectively. Solid, broken and dotted lines are calculated using the π -pulses of δ , 13.0 and 24.6 μs , respectively, together with the C–N interatomic distance of 2.48 Å¹⁵

length and finite lengths (13.0 and 24.6 μs) of the π pulse. It turns out, however, that the finite length of the ¹⁵N π pulse does not significantly affect the REDOR effect provided that the pulse length is less than 10% of the rotor cycle at the rotor frequency of 4000 Hz. This effect, however, should be seriously taken into account if fast MAS, e.g., 40 kHz is used.

For most spectrometers, it is difficult to be free from fluctuations of RF power during the acquisition of REDOR experiments. It is, therefore, critical that RF power be stabilized. If not, the π pulse will vary in length. Consequently, the REDOR factor is greatly decreased to yield relatively longer interatomic distances. Compensation of instability of such RF power, e.g., by approximate pulse sequence is, therefore, necessary to be free from long term fluctuations of amplifiers. xy-4 and xy-8 pulse sequences have been developed for this purpose. The xy-8 pulse is known to be the best sequence to compensate for the fluctuation of the RF power.²⁹

5.2 Contribution from Natural Abundance Nuclei

Since the early stages of the REDOR experiment, contributions from natural abundance nuclei have been seriously considered as a major source of error in the distance measurement.³⁰ It appears that the observed dipolar interaction can be modified by the presence of such neighboring naturally abundant nuclei. This effect was originally taken into account by simply calculating the $\Delta S/S_0$ value for two isolated pairs and adding proportionally to the natural abundant fraction.³⁰ Careful analysis of the three-spin system, however, indicates that this sort of simple addition of the fraction of the two-spin system may result in a serious overestimate of the natural abundance effect, to yield shorter distances.²³ The most accurate way to consider the natural abundance effect is, therefore, to treat the whole spin system as a three-spin system by taking into account the neighboring carbons in addition to the labeled pair. In practice, contributions from naturally abundant nuclei can be ignored for ¹³C REDOR but not for ¹⁵N REDOR, because the proportion of naturally abundant ¹³C nuclei is much higher than that of the ¹⁵N nuclei.²³

5.3 Sample Dilution

¹³C, ¹⁵N-doubly labeled samples are usually used in the REDOR experiment to determine the interatomic distances between the labeled nuclei. More importantly, the dipolar interaction with the labeled ¹⁵N nuclei for the neighboring molecules should be taken into account as an additional factor to contribute to the dipolar interaction of the observed pair under consideration. This contribution could be serious when the observed distance is quite remote, because there are many contributions from nearby nuclei. This effect can be completely removed by diluting the labeled sample with a sample of naturally abundant molecules.²³ The sensitivity of the signals, however, has to be sacrificed if one wants to remove the effect completely as the sample must be diluted to 1/49 so that the signal intensity is reduced by a factor roughly 0.02.¹¹ Instead, it is advised to evaluate the REDOR factors at the infinitely diluted condition by extrapolating the data by stepwise dilution of the sample (i.e., 60%, 30%, etc.) without losing sensitivity, because a linear relationship between the REDOR factor and the dilution is ascertained by a theoretical consideration.²³ Alternatively, the observed plots of $\Delta S/S_0$ values against the

corresponding NcTr values for the sample without dilution can be fitted by a theoretical curve obtained from the dipolar interactions among three-spin systems, although the accuracy is not always improved to the level of the dilution experiment.

5.4 T_2 Effect

The transverse magnetization of the REDOR experiment decays as a function of the ^1H decoupling field.^{31,32} Under appropriate conditions, molecular motion may interfere with dipolar decoupling. This occurs when molecular motion, if any, exists when the motional frequency is of the same order of magnitude as the decoupling field, and hence the transverse relaxation times (T_2) are significantly shortened. In fact, it was found that the T_2 values of the carbonyl carbons in crystalline Leu-enkephalin are relatively short because of the presence of backbone motion.³³ This is a serious problem for the REDOR experiment, especially for the long distance pairs, because the S/N ratio is significantly deteriorated. In this case, it is required to measure the ^{13}C REDOR signal under a sufficiently strong decoupling field to elongate the transverse relaxation times. It is also useful to perform measurements at low temperature so as to reduce the motional frequency. Note, however, that crystalline phase transitions might be associated together with the freezing of the solvent molecules. This effect has been observed in a variety of enkephalin samples.^{34,35}

5.5 RF Inhomogeneity and Confinement of the Sample within RF Coil

In the commercial spectrometer, the rotor is designed to allow the sample volume to be as large as possible in order to gain better sensitivity. Obviously, this arrangement causes H_1 inhomogeneity, which results in a broad distribution of the lengths of the 90° pulses. This problem is serious for the REDOR experiment in which a number of π pulses are applied. As a result, the pulse error can accumulate during the acquisition to give serious error in the measurements of internuclear distances. Particularly, the samples located at the top or bottom part of the sample rotor feel quite a weak RF field. This causes a great reduction of the REDOR factor for a sample that is filled all the way along the sample rotor.¹⁵ This effect should be seriously taken into account prior to experiments with a commercial spectrometer. It is, therefore, strongly recommended to fill the sample only in the central part of the coil just like a multiple pulse experiment to be able to acquire as accurate interatomic distances as possible in the REDOR experiment.

5.6 Standard Sample

All of the considerations mentioned above are essential to achieve accurate interatomic distances. Nevertheless, it is also possible that accuracy may deteriorate even if one of the conditions is not satisfied for every possible measurement. It is therefore advisable to determine the interatomic distances from a standard sample, in order to check that all the conditions are satisfied. More preferentially, use of two standard samples for short and long distances is recommended. In practice, it is recommended to use [$1\text{-}^{13}\text{C}$, ^{15}N]glycine as the former standard sample whose C–N interatomic distance is determined as 2.48 Å by a neutron diffraction study, and to check that all the instrumental conditions of a given spectrometer are satisfied prior to every new experiment. As a second standard sample for long distance, it is recommended to use [^{13}C , ^{15}N]N-acetyl-Pro-Gly-Phe (Table 1). This crystalline peptide is very stable with relatively long T_2 values, because it does not contain solvent molecules, and the presence of two polymorphic structures is well characterized.¹⁵

6 NATURAL ABUNDANCE ^{13}C REDOR EXPERIMENT²⁸

As mentioned already, it is impossible to obtain meaningful interatomic distances from a uniformly labeled sample as far as the standard REDOR procedure is concerned. Instead, the natural abundance REDOR experiment is more preferable as a means free from both homonuclear dipolar and scalar interactions (Figure 3). This approach provides the interatomic distances for a number of isolated spin pairs simultaneously under high resolution conditions. Further, this approach is free from the problem of the shortened T_2 values due to homonuclear ^{13}C spin interactions. Figure 5 shows the REDOR and full echo spectra of natural abundance ^{13}C nuclei of singly ^{15}N labeled crystalline ammonium [^{15}N]L-glutamate monohydrate (I) at NcTr = 8 ms, in contrast to the twisted spectra from the same sample uniformly labeled (Figure 3). The assignment of peaks to the C_β , C_γ , C_α , $\text{C}=\text{O}$ and C_δ carbon nuclei, from high to low field, is also shown in Figure 5. The $\text{C}=\text{O}$ (176.6 ppm) peak was distinguished from the C_δ (179.5 ppm) peak as a peak yielding a stronger REDOR effect as shown in Figure 5. Similarly, the peak at 56.0 ppm was assigned to the C_α carbon nucleus that give the strongest REDOR effect among the three aliphatic ^{13}C peaks. In a similar manner, the peak at 30.5 ppm showed a stronger REDOR effect compared

Table 1 C–N interatomic distances (Å) determined from REDOR experiments as compared with those by X-ray diffraction and MD¹⁵

Labeled peptides	Experimental			Calculated

^bRef.³⁶

^cData from Ref.²³ based on fully packed 7.5 mm rotor systems.

Figure 5 Naturally abundant ^{13}C -REDOR and full echo spectra at $\text{NcTr} = 8\text{ ms}$ with two different carrier frequencies for crystalline ammonium ^{15}N -L-glutamate monohydrate. Arrows indicate carrier frequency positions at the center of (a) $\text{C}=\text{O}$ and C_δ resonances; and (b) C_β and C_γ resonances

with that at 35.2 ppm. Thus, the peaks at 35.2 and 30.5 ppm were assigned to the C_γ and C_β carbon nuclei, respectively.

The interatomic C–N distances between ^{15}N and $^{13}\text{C}=\text{O}$, $^{13}\text{C}_\alpha$, $^{13}\text{C}_\beta$, $^{13}\text{C}_\gamma$, and $^{13}\text{C}_\delta$ carbon nuclei were determined with accuracy of 0.15 Å, after experimental conditions were carefully optimized. ^{13}C -REDOR factors for a three-spin system, $(\Delta S/S_0)_{\text{CNIN}_2}$, and the sum of two isolated two-spin systems, $(\Delta S/S_0)^* = (\Delta S/S_0)_{\text{CN}_1} + (\Delta S/S_0)_{\text{CN}_2}$, were further evaluated by the REDOR measurements on isotopically diluted I in a controlled manner. Subsequently, the intramolecular and intermolecular C–N distances were separated by searching the minimum in the contour map of the root mean square deviation (RMSD) between the theoretically and experimentally obtained $(\Delta S/S_0)^*$ values against two interatomic distances, $r_{\text{C-N}_1}$ and $r_{\text{C-N}_2}$. When the intramolecular C–N distance ($r_{\text{C-N}_1}$) of the particular carbon nucleus is substantially shorter than the intermolecular distance ($r_{\text{C-N}_2}$), C–N distances between the molecule in question and the nearest neighboring molecules can also be obtained, although accuracy is inevitably deteriorated. On the other hand, it was difficult to determine the interatomic distances in the same molecule

when the intermolecular dipolar contribution is larger than the intramolecular one as in the case of the C_δ carbon nucleus.

7 ACCURACY LIMIT FOR REDOR STRUCTURE OF PEPTIDE AND PROTEINS

Naito et al.¹⁵ systematically applied this technique to elucidate the three-dimensional structure of *N*-acetyl-Pro-Gly-Phe. They proposed that the carbonyl carbon of the (*i*–1)th residue and the amino nitrogen of the (*i*+1)th residue should be labeled with ^{13}C and ^{15}N , respectively. Namely, $[1-^{13}\text{C}]\text{N-acetyl-Pro-}^{15}\text{N-Gly-Phe(I)}$, *N*-acetyl- $[1-^{13}\text{C}]\text{Pro-Gly-}^{15}\text{N-Phe(II)}$ and $[1-^{13}\text{C}]\text{N-acetyl-Pro-Gly-}^{15}\text{N-Phe(III)}$ were synthesized and the resulting distances were determined to be 3.24 ± 0.05 , 3.43 ± 0.05 , and 4.07 ± 0.05 Å respectively, utilizing the REDOR factor obtained for the infinitely diluted state to prevent errors from the contributions of the neighboring labeled nuclei. No correction from the contribution of the naturally abundant nuclei turned out to be necessary. Surprisingly, these distances do not agree well with the values obtained from an X-ray diffraction study available when the initial part of this experiment was performed, showing the maximum discrepancy between them to be 0.5 Å.³⁶ This value seems to be much larger than the expected error as estimated from the precision of the REDOR experiment (± 0.05 Å). The reason why the discrepancy is unexpectedly larger was explained by the fact that the crystal (orthorhombic) used for the REDOR experiments is different from that used in the X-ray diffraction study (monoclinic). To check the accuracy of the REDOR experiment, an X-ray diffraction study was performed on the same crystals used for the REDOR experiment. It was found that the distances from the new crystalline polymorph (orthorhombic) agree well between REDOR and X-ray diffraction, within an accuracy of 0.05 Å as shown in Table 1.

Conformational maps based on the possible combinations of the torsion angles of the Pro and Gly residues are calculated on the basis of the distance constraints thus obtained. Further, the difference of the chemical shifts between the C_β and C_γ carbons of the Pro residues $\Delta\beta\gamma$ was used as a constraint to determine the ψ value (-13°).³⁷ The ϕ angle of the Pro residue is in many instances restricted to -75° which shows the minimum energy in the residue. Therefore, the torsion angles of the Pro residue are uniquely determined to be (-75° , -28°). Using these torsion angles, conformational maps were again calculated. Finally two pairs of torsion angles were selected as (-112° , 48°) and (-112° , -48°). Minimization by a molecular mechanics calculation yielded the structure of the β -turn I structure, as shown in Figure 6(a). It is found that the three-dimensional structure of this peptide is well reproduced by a molecular dynamics simulation by taking into account all of the intermolecular interactions in the crystals, although a molecular dynamics calculation treating *single* molecular system does not always yield a correct picture as illustrated in Figure 6(b), unless otherwise all the molecules in a unit cell are correctly taken into account.^{15,38}

Elucidation of the three dimensional structure of an opioid peptide Leu-enkephalin crystal, Tyr-Gly-Gly-Phe-Leu grown from MeOH/H₂O mixed solvent was performed by the REDOR method alone.¹⁶ This seems to be an additional challenge for this technique to reveal the three-dimensional structure of more complicated systems. Six differently labeled

Figure 6 Optimized conformation of *N*-acetyl-Pro-Gly-Phe as obtained by the minimization of energy from the initial form as deduced from the REDOR experiment (a) and a snapshot of the conformation deduced by MD simulation in vacuo (at 100 K) (b)¹⁵

Leu-enkephaline molecules were synthesized and the resulting interatomic distances (Figure 7a) are accurately determined. It turns out, however, that an extremely careful experiment is required to avoid unexpected crystalline conversion among polymorphs either by dehydration from a tightly sealed rotor or a phase transition occurring at ambient temperature. In

principle, pressure under MAS may shift a temperature of phase transition to some extent, because centrifugal force is proportional to the square of the spinning frequency. No significant effect, however, has been noted so far as a sample is spun at relatively low frequency such as 2–4 kHz but care might be taken when rotor is spun at a frequency one order of magnitude high as in 40 kHz.

This may be the reason why final refinement of X-ray diffraction data was abandoned in spite of the pioneering X-ray diffraction data as to the similarity of the tertiary structure between this opioid peptide and morphine.³⁹ Therefore, it is necessary to check whether the six differently labeled samples are all in the same crystalline polymorph by means of the ¹³C chemical shifts. Otherwise, meaningless data can be obtained without this precaution. When the distance data are converted to yield the necessary numbers of torsion angles, a unique combination of torsion angles in the corresponding conformational map is determined sequentially as shown in Figure 7(b). It is emphasized that accuracy within 0.1 Å is essential to select unique torsion angles for each amino acid residue. Namely, if the error is larger than 0.41 Å, torsion angles can no longer be selected as shown in Figure 8.

It is also important to point out that the chemical shift data can be used as additional constraints. A three dimensional structure was thus determined as shown in Figure 9. However, this structure is not the same as that previously determined

Figure 7 (a) Schematic representation between the sites of a variety of [¹³C, ¹⁵N]-doubly-labeled Leu-enkephalin dehydrates and their related torsion angles. (b) Block diagram to show how respective torsion angles are uniquely determined by the combined examinations of the conformation maps based on the distances of four-bonds apart (I, II, III and VI) and five-bonds apart (IV and V)¹⁶

Figure 8 Conformation maps for $(\Psi_{\text{Gly2}}, \omega_{\text{Gly2}})$ based on the interatomic distance of 4.55 Å with increased experimental errors: (a) ± 0.10 Å, (b) ± 0.20 Å, and (c) ± 0.41 Å¹⁶

by X-ray diffraction because one is dealing with a crystalline polymorph that is not fully explored. It is possible to figure out the molecular packing in the crystals by looking at the intermolecular dipolar contribution. Since the intermolecular dipolar contributions in I and III are larger than that of II, a β -sheet is formed as one peptide interacts with two peptides as an antiparallel β -sheet as shown in Figure 9(b).

Finally, it should be pointed out that, in order to isolate an S–I spin pair, it is essential to avoid any unnecessary errors from dipolar contributions of neighboring molecules from the overall S–I_n spin system. This is generally encountered for a variety of peptides and the aforementioned dilution procedure turned out to be not required in the case of α -helical polypeptides as far as the measurement of the interatomic distance for $^{15}\text{NH}(i) \cdots \text{O} = ^{13}\text{C}(i+4)$ is concerned.⁴⁰ This is because the interhelical dipolar contribution is found to be negligible in view of the mutual packing of α -helical chains or random mutual orientation between isotopically labeled atoms. Further, it was found that in helical peptides, due to the manner of chain packing, this kind of measurement is feasible to yield 4.5 ± 0.1 Å, without any assumptions, for a variety of transmembrane α -helical peptides in lipid bilayers to mimic a biomembrane at a temperature below liquid crystalline-gel phase transition at which rotation of such peptides about the α -helical axis turns out to be frozen, in spite of the presence

Figure 9 (a) Three-dimensional structure of Leu-enkephalin dihydrate determined uniquely by the successive application of the conformation maps as well as additional constraints of the conformation-dependent ^{13}C chemical shifts. (b) Three kinds of models for putative intermolecular packing as illustrated in the cartoons: (1) interaction through parallel β -sheet form; (2) interaction through an antiparallel β -sheet; and (3) interaction through interaction of three molecules. Solid and dotted arrows correspond with the dipolar interactions between intramolecular ^{13}C – ^{15}N pairs, respectively¹⁶

of rotational motions of lipid molecules, as viewed from the observation of three principal components of ^{13}C and ^{31}P chemical shift tensors.⁴¹ As is shown in this example, it is essential to ensure that molecular motion is reasonably ceased.

8 CONCLUSIONS

REDOR is one of the most powerful methods to determine accurate interatomic distances after taking into account a number of points in applying the method to a practical sample. Simultaneous measurement of interatomic distances using uniformly labeled samples can only be achieved by removing the homonuclear dipolar and scalar interactions. Alternatively, natural abundance ^{13}C REDOR measurements provide interatomic distances simultaneously free from homonuclear dipolar and scalar interactions. These accurate interatomic distances obtained from REDOR experiments can provide important information on structure and molecular packing of solid peptides and proteins.

1 INTRODUCTION

Shortly after its first detection in condensed matter in 1945,^{1,2} it became evident that NMR was an extremely sensitive probe of the local electronic environments of magnetic nuclei. Some of the first observations of NMR uncovered a chemical effect on the relative resonance frequencies of identical nuclear isotopes which has come to be known as the chemical shift, and because of this effect NMR has evolved into one of the premier spectroscopic techniques for chemical structure analysis. The primary use of NMR consists of measuring the isotropic chemical shifts of nuclei imbedded in molecules dissolved in solution; however, important information about the anisotropy of this interaction is available from the spectra of solids.³⁻⁵

Certain characteristics of the anisotropic chemical shift, the principal values of the chemical shift tensor for example, can be obtained from the spectra of powdered samples and, to a lesser extent, from molecules dissolved in liquid crystal solvents. Nevertheless, single crystal samples are preferred, when available, as they allow direct measurements of the complete chemical shift tensor. Single crystals are especially useful for studies of large molecules where the many overlapping powder patterns in traditional one-dimensional (1D) spectra are uninterpretable and where selectively labeling each individual site is impractical. Although progress has been made in extracting principal values from powdered samples of large molecules using two-dimensional (2D) NMR methods,⁶ direct measurements of tensor orientations can be made only on single crystals.

This article is written as an introduction to the techniques that are available for measuring chemical shift tensors in single crystals. Although many aspects of the techniques are quite general, the emphasis here will be on measurements of ¹³C chemical shift tensors in organic systems.

The first measurement of a ¹³C chemical shift tensor was made in the very early days of ¹³C NMR by Lauterbur⁷ on the carbonate ion of single crystal calcite (CaCO₃). This particular sample proved to be ideal because all magnetic nuclei were at

low abundance and thus the dipolar broadening was negligible. A few other systems were exploited where similar dilution occurred naturally or was introduced by substitution of ²D for ¹H, but progress along these lines was limited. It was only after the introduction of the combined cross polarization and high-power dipolar decoupling techniques⁸ that ¹³C chemical shift tensor measurements became more generally applicable. One of the first demonstrations of these now widely used techniques was in the measurement of ¹³C chemical shift tensors in single crystal durene (1,2,4,5-tetramethylbenzene).⁹

2 NUCLEAR SHIELDING AND THE CHEMICAL SHIFT TENSOR

The fundamental equation relating the NMR resonance frequency and the magnetic field strength is well known to all students of magnetic resonance

$$\nu_0 = |\gamma/2\pi|B_0 \quad (1)$$

For ¹³C, this frequency corresponds to 50 MHz in a typical field of 4.7 T.

Due to the electronic circulation set up in a molecule by the applied magnetic field, the effective field experienced by a particular nucleus is not exactly equal to B_0 . The electronic 'currents' induce a small shielding field B_s which must be added to B_0 to obtain the effective field at the nucleus

$$B_{\text{eff}} = B_0 + B_s \quad (2)$$

This vector addition is shown schematically in Figure 1.

Although B_s is called the shielding field, it does not necessarily oppose B_0 and thus deshieldings or paramagnetic shifts are possible. In general, the direction of B_s is not parallel to B_0 but the two are related through the shielding tensor which is represented as the 3×3 matrix σ

$$B_s = -\sigma \cdot B_0 \quad (3)$$

Figure 1 The relationship between the applied field B_0 , the shielding field B_s and the effective field B_{eff}

2 CHEMICAL SHIFT TENSORS IN SINGLE CRYSTALS

The matrix σ is usually called a second rank Cartesian tensor although it also contains zeroth and first rank parts as well.

Since B_s is very small compared to B_0 , equation (2) can be closely approximated by adding only the component of B_s that is either parallel or antiparallel to B_0 to obtain

$$B_{\text{eff}} = B_0 - \frac{B_0}{B_0} \cdot \sigma \cdot B_0 \quad (4)$$

The above approximation is equivalent to *truncation* or restriction to the *secular* terms of the chemical shift Hamiltonian in first-order perturbation theory. It should be pointed out that σ can be decomposed into a sum of second rank symmetric and first rank antisymmetric constituents

$$\sigma = \sigma^S + \sigma^A \quad (5)$$

Since σ^A leads to components of B_s which are perpendicular to B_0 , it does not contribute to B_{eff} in first order and thus its effect on the resonance frequency of the nucleus can be ignored.

The effect of shielding is thus to change the precession frequency of the nucleus from ν_0 to the frequency given by

$$\nu = |\gamma/2\pi| B_{\text{eff}} \quad (6)$$

In practice, the frequency of the bare nucleus is not known, and measurements of the frequency ν are always made relative to a reference frequency ν_{ref} , which for ^{13}C is usually taken as the resonance of liquid tetramethylsilane (TMS). The frequency difference between sample and reference can be written as

$$\nu - \nu_{\text{ref}} = |\gamma/2\pi| \frac{B_0}{B_0} \cdot (\sigma^S - \sigma_{\text{ref}} \mathbf{1}) \cdot B_0 \quad (7)$$

where σ_{ref} is the isotropic chemical shielding constant of the reference compound and $\mathbf{1}$ is the unit matrix. The symmetric difference matrix $(\sigma^S - \sigma_{\text{ref}} \mathbf{1})$ is defined as the chemical shift tensor, and is assigned the symbol δ in order to avoid its confusion with the shielding tensor σ .

It is customary to report chemical shifts not as frequencies, since these always depend on B_0 which varies from one spectrometer to the next, but as fractions of ν_{ref} . If the chemical shift F is defined as $(\nu - \nu_{\text{ref}})/\nu_{\text{ref}}$, then

$$F = \frac{B_0}{B_0} \cdot \delta \cdot \frac{B_0}{B_0} \quad (8)$$

Equation (8) is the master equation for the chemical shift in a single crystal, as it gives the observed shift in terms of the elements of δ and the orientation of B_0 .

For elements with sufficiently low atomic numbers, the chemical shift tensor δ can be represented in a Cartesian coordinate system as a 3×3 symmetric matrix

$$\delta = \begin{bmatrix} \delta_{xx} & \delta_{xy} & \delta_{zx} \\ \delta_{xy} & \delta_{yy} & \delta_{yz} \\ \delta_{zx} & \delta_{yz} & \delta_{zz} \end{bmatrix} \quad (9)$$

The matrix δ is called the Cartesian representation of the chemical shift tensor and is completely defined by

six independent numbers. It will be seen below that other representations are possible.

The average value of δ is known as the isotropic chemical shift

$$\delta_{\text{iso}} = \frac{1}{3}(\delta_{xx} + \delta_{yy} + \delta_{zz}) \quad (10)$$

and it is only this part of the chemical shift tensor which can be directly measured in solution samples due to rapid isotropic tumbling of the molecules. The isotropic chemical shift is also called the zeroth rank part of δ since it transforms as a scalar quantity, i.e., it is invariant under rotation.

A Cartesian tensor can be expressed in a different coordinate system by performing a similarity transformation on the matrix δ

$$\delta' = \mathbf{R} \delta \mathbf{R}^T \quad (11)$$

where $\mathbf{R}$ is a unitary matrix. The element R_{ij} is given by the direction cosine of the i th new coordinate axis with respect to the j th old coordinate axis. For instance, $R_{12} = \cos \gamma_{x'y}$ where $\gamma_{x'y}$ is the angle between the new x axis and the old y axis.

A number of coordinate systems are necessary in single crystal work. The *laboratory frame* is a coordinate system whose z axis lies along the direction of the static magnetic field. Rather than working in the laboratory frame, it is usually more convenient to work in a coordinate system called the *sample frame* whose orientation is fixed with respect to the single crystal sample. The sample frame will always be the coordinate system in which tensors are measured. A third coordinate system is that defined by the symmetry elements of the crystal and this will be called the *crystal frame*. The orientation of the crystal frame relative to the sample frame can usually be found by diffraction methods. For molecules containing high symmetry, it is often useful to define a coordinate system based on molecule symmetry elements called the *molecular frame*. For molecules of low symmetry, coordinate systems can be defined based on the local symmetry of a particular nuclear site and these will be called *local frames*. Finally, there is an important coordinate system known as the *principal axis* system which is unique to each tensor. The principal axis system is discussed below.

The relationships between all of these reference frames, except for that between the sample frame and laboratory frame, are determined by the crystal and molecular structure, and therefore they are not under experimental control. It is clear from equation (11) that once the tensor is known in one of these reference frames, it can be expressed in any of the other frames provided the unitary matrix $\mathbf{R}$ is available.

For any symmetric second rank tensor such as the chemical shift tensor δ , there exists a unitary matrix $\mathbf{S}$ that transforms δ into a coordinate system in which it is diagonal

$$\mathbf{S} \delta \mathbf{S}^T = \mathbf{\Lambda} \quad (12)$$

where $\mathbf{\Lambda}$ is a diagonal matrix with elements λ_1 , λ_2 , and λ_3 . This special coordinate system is called the principal axis system and the diagonal tensor elements are called the principal values. Multiplying both sides of equation (12) by $\mathbf{S}^{-1} = \mathbf{S}^T$ yields

$$\delta \mathbf{S}^T = \mathbf{S}^T \mathbf{\Lambda} \quad (13)$$

Equation (13) is readily recognized as an algebraic eigenvalue equation and the eigenvalues (principal values) and eigenvectors (principal axes) can be found by solving the secular equation

$$|\delta - \Lambda \mathbf{I}| = \begin{vmatrix} \delta_{xx} - \lambda_1 & \delta_{xy} & \delta_{zx} \\ \delta_{xy} & \delta_{yy} - \lambda_2 & \delta_{yz} \\ \delta_{zx} & \delta_{yz} & \delta_{zz} - \lambda_3 \end{vmatrix} = 0 \quad (14)$$

A convention for labeling the principal values is generally followed in which they are designated δ_{11} , δ_{22} , and δ_{33} in order of decreasing chemical shift. An alternative to the Cartesian representation of a chemical shift tensor is its representation as three principal values and the three Euler angles that orient the principal axis system with respect to one of the coordinate systems defined above. Other useful representations of the chemical shift tensor are described elsewhere.¹⁰

Recalling equation (8), the chemical shift F observed when the magnetic field is oriented with direction cosines $\cos \gamma_x$, $\cos \gamma_y$, and $\cos \gamma_z$ relative to the sample frame axes can be explicitly written as the quadratic form

$$\begin{aligned} F &= [\cos(\gamma_x) \cos(\gamma_y) \cos(\gamma_z)] \begin{bmatrix} \delta_{xx} & \delta_{xy} & \delta_{zx} \\ \delta_{xy} & \delta_{yy} & \delta_{yz} \\ \delta_{zx} & \delta_{yz} & \delta_{zz} \end{bmatrix} \begin{bmatrix} \cos(\gamma_x) \\ \cos(\gamma_y) \\ \cos(\gamma_z) \end{bmatrix} \\ &= \cos^2(\gamma_x) \delta_{xx} + \cos^2(\gamma_y) \delta_{yy} + \cos^2(\gamma_z) \delta_{zz} \\ &\quad + 2 \cos(\gamma_x) \cos(\gamma_y) \delta_{xy} + 2 \cos(\gamma_y) \cos(\gamma_z) \delta_{yz} \\ &\quad + 2 \cos(\gamma_z) \cos(\gamma_x) \delta_{zx} \end{aligned} \quad (15)$$

It is seen from equation (15) that if the chemical shift tensor δ is known in the sample frame, the chemical shift can be calculated for any orientation of $\mathbf{B}_0$. Alternatively, if the chemical shift F is known for six suitably chosen directions of $\mathbf{B}_0$, the elements of δ can be obtained by solving a system of linear equations.

Equation (15) takes on a particularly simple form when expressed in the principal axis system

$$F = \cos^2(\gamma_x) \delta_{11} + \cos^2(\gamma_y) \delta_{22} + \cos^2(\gamma_z) \delta_{33} \quad (16)$$

Provided that the reference frequency is chosen such that the three principal values δ_{11} , δ_{22} , and δ_{33} are positive, a connection can be made between equation (16) and the equation of an ellipsoid with semiaxes a , b , and c

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1 \quad (17)$$

The direction cosines of a radius vector $\mathbf{r}$ taken from the origin to a point on the surface of the ellipsoid are given by $\cos^2(\gamma_x) = x^2/r^2$, $\cos^2(\gamma_y) = y^2/r^2$, and $\cos^2(\gamma_z) = z^2/r^2$. Substituting these into equation (17) yields

$$\frac{r^2 \cos^2(\gamma_x)}{a^2} + \frac{r^2 \cos^2(\gamma_y)}{b^2} + \frac{r^2 \cos^2(\gamma_z)}{c^2} = 1 \quad (18)$$

Finally, by making the identities $a^2 = 1/\delta_{11}$, $b^2 = 1/\delta_{22}$, and $c^2 = 1/\delta_{33}$, equation (18) can be rearranged to give

$$\cos^2(\gamma_x) \delta_{11} + \cos^2(\gamma_y) \delta_{22} + \cos^2(\gamma_z) \delta_{33} = \frac{1}{r^2} \quad (19)$$

Figure 2 The chemical shift tensor representation ellipsoid

The surface described by equation (19) is called the representation ellipsoid¹¹ of the chemical shift tensor and is illustrated in Figure 2.

The semiaxes of the ellipsoid are given by $1/\sqrt{\delta_{11}}$, $1/\sqrt{\delta_{22}}$, and $1/\sqrt{\delta_{33}}$. Comparing equation (16) and (19), it is seen that when $\mathbf{B}_0$ is oriented along $\mathbf{r}$, the length of the radius vector is given by $r = 1/\sqrt{F}$.

The representation ellipsoid thus allows a geometrical interpretation of the chemical shift tensor, and the *mmm* (D_{2h}) symmetry of this object reflects the symmetry of the chemical shift interaction.

In order to understand the effect of crystallographic symmetry on the chemical shift, it is necessary to define some terminology. Nuclear sites related by the rotation or reflection symmetry operations of the space group of the crystal are called *crystallographically equivalent* sites. Those sites that are related by inversion or translation are called *magnetically equivalent* sites. This definition of magnetic equivalence is in contrast to that used in solution NMR where sites related by any symmetry element of the molecule are magnetically equivalent due to the rapid isotropic tumbling of the molecule. As the operations of either inversion or translation do not change the orientation of the representation ellipsoid, a set of magnetically equivalent sites gives rise to a single peak in the spectrum. On the other hand, the representation ellipsoids of crystallographically equivalent sites are oriented differently in the absence of accidental coincidence of the symmetry elements of the representation ellipsoid with those of the space group. Therefore, multiple peaks occur in the spectrum of a single crystal sample when the magnetic field is in a general orientation with respect to a lattice of crystallographically equivalent sites. Two tensors are said to be *congruent* if they are each associated with nuclear sites which are crystallographically equivalent. Congruent tensors have identical principal values, but differ in the orientations of their respective principal axes.

3 THE SINGLE AXIS ROTATION METHOD

In the case of a crystal containing only one set of magnetically equivalent nuclei, the measurement technique is straightforward since the spectrum of such a crystal contains a single peak in any orientation of the field. Six 1D spectra can be obtained with the magnetic field oriented along six different directions. The chemical shift derived from each spectrum, along with the corresponding direction cosines describing

the orientation of the magnetic field, is then substituted into equation (15) to obtain a set of six equations from which the tensor elements are extracted.

The spectrum of a sample containing multiple sets of magnetically equivalent nuclei has a corresponding multiplicity of peaks. In this case the six 1D spectra described above would be useless, since there would be no way to determine which peak in each of the spectra was from a particular set of magnetically equivalent nuclei. One solution to this problem is to acquire many 1D spectra which differ by small angle rotations of the crystal so that the paths of the lines can be traced from one spectrum to the next to form a *rotation pattern*.

Consider a rotation of the crystal about an axis that makes an angle β with the magnetic field $\mathbf{B}_0$. The arbitrary sample frame can be oriented such that the x axis is parallel to the rotation axis and the magnetic field $\mathbf{B}_0$ lies initially in the xy plane. If the crystal is rotated through an angle α , the direction cosines of the field with respect to the sample frame are given by

$$\cos(\gamma_x) = \cos(\beta) \quad (20)$$

$$\cos(\gamma_y) = \sin(\beta) \cos(\alpha) \quad (21)$$

$$\cos(\gamma_z) = \sin(\beta) \sin(\alpha) \quad (22)$$

It can easily be shown by substituting equations (20)–(22) into equation (15) that the chemical shift F is given by

$$F = A + B \cos(\alpha) + C \sin(\alpha) + D \cos(2\alpha) + E \sin(2\alpha) \quad (23)$$

where

$$A = \frac{1}{2} \sin^2(\beta) (\delta_{yy} + \delta_{zz}) + \cos^2(\beta) \delta_{xx} \quad (24a)$$

$$B = 2 \sin(\beta) \cos(\beta) \delta_{xy} \quad (24b)$$

$$C = 2 \sin(\beta) \cos(\beta) \delta_{zx} \quad (24c)$$

$$D = \frac{1}{2} \sin^2(\beta) (\delta_{yy} - \delta_{zz}) \quad (24d)$$

$$E = \sin^2(\beta) \delta_{yz} \quad (24e)$$

From equation (23) it is seen that if the chemical shift is observed at five different angles α , for a given angle β , the coefficients A , B , C , D , and E can be extracted. However, these five coefficients are insufficient to determine fully the six tensor elements and it is apparent that the complete chemical shift tensor cannot be measured from a single rotation pattern.

The most frequently used measurement technique is to obtain three patterns by rotating the crystal about a single axis perpendicular to $\mathbf{B}_0$ in the laboratory frame as depicted in Figure 3.

Figure 3 Schematic representation of a simple experimental set-up for obtaining single axis rotation patterns

The three rotation patterns are obtained first with the x , then the y , and finally the z sample frame axis along the rotation direction. The rotation pattern about the x axis is easily obtained from equations (23) and (24) by setting the angle β equal to $\pi/2$

$$F(\alpha_x) = \frac{1}{2}(\delta_{yy} + \delta_{zz}) + \frac{1}{2}(\delta_{yy} - \delta_{zz}) \cos(2\alpha_x) + \delta_{yz} \sin(2\alpha_x) \quad (25)$$

The other two rotation patterns can be found by cyclic permutation of the sample axis labels x , y , and z

$$F(\alpha_y) = \frac{1}{2}(\delta_{zz} + \delta_{xx}) + \frac{1}{2}(\delta_{zz} - \delta_{xx}) \cos(2\alpha_y) + \delta_{zx} \sin(2\alpha_y) \quad (26)$$

$$F(\alpha_z) = \frac{1}{2}(\delta_{xx} + \delta_{yy}) + \frac{1}{2}(\delta_{xx} - \delta_{yy}) \cos(2\alpha_z) + \delta_{xy} \sin(2\alpha_z) \quad (27)$$

Although each rotation pattern is fully determined by measuring the chemical shift at only three different angles, the usual practice is to obtain spectra at many angles by stepping the goniometer from 0° to 180° , and to extract the tensor elements using least-squares methods. This allows a more accurate determination of the tensor and is a necessity if the spectrum of the crystal contains many peaks, since the path of a single peak can be traced only when the crystal is rotated in small angular increments. In order to obtain all six elements of the chemical shift tensor for a particular set of magnetically equivalent nuclei, the path of the corresponding peak must not only be traced within each rotation but must also be traced between rotations. This is accomplished by matching up the rotation patterns at the orientations where they intersect. Figure 4 shows three rotation patterns from which the ^{13}C chemical shift tensors of naphthalene can be obtained.

The rotation method has been successfully applied to many medium-sized molecules;¹² however, it fails when the peaks in the spectra become numerous and crowded since it becomes impossible to trace the paths of individual peaks through the three rotation patterns. Another drawback of the rotation method is the necessity of accurately mounting the crystal three times along the three orthogonal sample axes, but this problem has been overcome using a two-axis goniometer and a unique rf coil as demonstrated by Hauser et al.¹³

Figure 4 Rotation patterns through 180° about the x , y , and z sample axis sufficient to measure the 10 chemical shift tensors in single crystal naphthalene

4 SINGLE AXIS 2D CHEMICAL SHIFT TENSOR CORRELATION SPECTROSCOPY

The necessity of taking small angular increments in the rotation patterns can be eliminated using a 2D correlation method introduced by Carter et al.¹⁴ This technique obtains 2D spectra in which a peak from a single set of magnetically equivalent nuclei is located by its resonant frequencies at two different orientations of the single crystal. Such spectra are obtained with the modified 2D chemical exchange¹⁵ pulse sequence shown in Figure 5.

The preparation period of this sequence is identical to the usual cross-polarization experiment. During the evolution period, the spins precess at frequencies determined by their chemical shifts at the initial crystal orientation. The evolved magnetization is then stored along the z axis with the pulse labeled b and the crystal is reoriented during the mixing period. At the end of the mixing period, the stored magnetization is rotated back to the transverse plane with the pulse labeled a , and during the detection period the spins precess at frequencies determined by their chemical shifts at the final crystal orientation. An example of a 2D chemical shift tensor correlation spectrum is shown in Figure 6 where all 24 peaks in

Figure 5 Modified chemical exchange sequence for 2D chemical shift tensor correlation spectroscopy. See text for details. (Reproduced by permission of Academic Press from M. H. Sherwood, D. W. Alderman, and D. M. Grant, *J. Magn. Reson.*, 1989, **84**, 466)

Figure 6 Two-dimensional absorption mode spectrum obtained from sucrose corresponding to a reorientation of B_0 by 90° in the sample frame. The plotted spectral width is $5 \text{ kHz} \times 5 \text{ kHz}$ (approximately $100 \text{ ppm} \times 100 \text{ ppm}$). The spectrum diagonal runs from upper left (high frequency) to lower right (low frequency). (Adapted by permission of Academic Press from M. H. Sherwood, D. W. Alderman, and D. M. Grant, *J. Magn. Reson.*, 1989, **84**, 466)

single crystal sucrose are resolved despite the severe crowding that exists in the corresponding 1D spectra.

It has been shown that the information present in one rotation pattern can be obtained from four 2D spectra taken while stepping the sample from 0° to 45° , 45° to 90° , 90° to 135° , and 135° to 180° (equivalent to 0°).¹⁶ The redundancy in this information permits a powerful square construction which resolves the uncertainties due to peak overlap within each rotation. However, this single axis 2D technique does

not address the problem of joining the three rotation patterns together when there are many overlapping lines in the spectra at the orientations where the patterns intersect. Thus the application of the single axis 2D method is limited to samples where the connections can be made by conventional means. As in the traditional 1D method, it is necessary to mount the sample accurately three times for the single axis 2D measurements.

5 MULTIPLE AXIS 2D CHEMICAL SHIFT TENSOR CORRELATION SPECTROSCOPY

The full power of the 2D technique can be realized by gathering data in such a way that all correlations between required crystal orientations are obtained with a single mounting of the crystal. This is accomplished with a multiple axis sample orienting mechanism which complements the 2D method to form an exceedingly powerful technique for measuring chemical shift tensors in complex single crystals.¹⁷

As mentioned above, the six independent elements of a chemical shift tensor, in principle, can be determined by measuring the chemical shift with the magnetic field oriented along six suitably chosen directions. Table 1 gives the orientations of six such directions in the sample frame.

Table 1 Six Magnetic Field Directions in the Sample Frame That can be Used to Measure a Chemical Shift Tensor

Magnetic field direction	$\cos(\gamma_X)$	$\cos(\gamma_Y)$	$\cos(\gamma_Z)$	Observed shift
X	1	0	0	F_X
XY	$1/\sqrt{2}$	$1/\sqrt{2}$	0	F_{XY}
Y	0	1	0	F_Y
YZ	0	$1/\sqrt{2}$	$1/\sqrt{2}$	F_{YZ}
Z	0	0	1	F_Z
ZX	$1/\sqrt{2}$	0	$1/\sqrt{2}$	F_{ZX}

These directions lie on the surface of a trigonal pyramid and will be referred to here as the pyramidal directions. The observed chemical shifts F_X , F_{XY} , F_Y , F_{YZ} , F_Z , and F_{ZX} are easily calculated from equation (15), yielding the relationships

$$F_X = \delta_{xx} \quad (28a)$$

$$F_{XY} = \delta_{xy} + \delta_{xx}/2 + \delta_{yy}/2 \quad (28b)$$

$$F_Y = \delta_{yy} \quad (28c)$$

$$F_{YZ} = \delta_{yz} + \delta_{yy}/2 + \delta_{zz}/2 \quad (28d)$$

$$F_Z = \delta_{zz} \quad (28e)$$

$$F_{ZX} = \delta_{zx} + \delta_{zz}/2 + \delta_{xx}/2 \quad (28f)$$

which trivially invert to

$$\delta_{xx} = F_X \quad (29a)$$

$$\delta_{xy} = F_{XY} - F_X/2 - F_Y/2 \quad (29b)$$

$$\delta_{yy} = F_Y \quad (29c)$$

$$\delta_{yz} = F_{YZ} - F_Y/2 - F_Z/2 \quad (29d)$$

$$\delta_{zz} = F_Z \quad (29e)$$

$$\delta_{zx} = F_{ZX} - F_Z/2 - F_X/2 \quad (29f)$$

By obtaining the six 2D spectra corresponding to reorientation between the X - XY , XY - Y , Y - YZ , YZ - Z , Z - ZX , and ZX - X direction pairs, the correlation data are sufficient to determine the complete chemical shift tensors for all of the sets of magnetically equivalent nuclei in the sample. Starting first with the X - XY 2D spectrum, the chemical shifts of the X and XY directions are measured and correlated. Then the observed chemical shifts in the XY direction from the X - XY spectrum are matched with those from the XY - Y spectrum to advance the correlation of the chemical shift to the Y direction, and so forth through YZ , Z , ZX , and back to X . After completion of the full cycle of reorientations, the chemical shift is known for each set of magnetically equivalent nuclei at all six orientations and the tensor elements can be calculated from equations (29a)–(29f). The correlation of chemical shifts around the full cycle forms the closed path depicted in Figure 7(a).

It may be noted that the sense of the reorientation is unimportant. The same frequency information is obtained by reorienting from the X to the XY direction as is obtained by reorienting from XY to X . The only consequence is to interchange the F_1 and F_2 axes of the spectrum.

A powerful criterion, analogous to the square construction described for the single axis 2D approach, allows the correlation of peaks which have identical frequencies at one or more of the six magnetic field directions. It employs reorientations between other pairs of the six measurement directions. The full matrix of 36 possible 2D correlation spectra is shown in Figure 7(b). The 2D spectra that lie along the diagonal of this matrix correspond to trivial correlations between two identical orientations, and are thus of no experimental value. The spectra related by the transpose of this matrix differ only by the sense of the reorientation, and contain the same correlation information. Therefore, only 15 of the 36 possible spectra are necessary to obtain all of the available correlation and frequency information. The spectra matrix construction allows the chemical shifts of a single set of magnetically equivalent nuclei to be traced through all 15 possible 2D correlation spectra simply by connecting the peaks with horizontal and vertical lines as shown in Figure 7(b).

A mechanism which accomplishes the 15 flips has been described in detail elsewhere.¹⁷ Briefly, it consists of an armature into which a glass tube containing the sample is

Figure 7 Matrix of 2D spectra. (a) Six 2D spectra corresponding to $XY-X$, $XY-Y$, $YZ-Y$, $YZ-Z$, $ZX-Z$, and $ZX-X$ reorientations. The relationship of the peaks in these spectra is shown for a single set of magnetically equivalent nuclei by the vertical and horizontal connecting lines. Dotted lines indicate the diagonals in the spectra. (b) All 36 possible 2D spectra. The relationship of the peaks in the spectra is shown for a single set of magnetically equivalent nuclei by the vertical and horizontal connecting lines. The six unshaded spectra with dotted diagonals correspond to those of Figure 7(a). The six darkly shaded spectra with solid diagonals are the trivial autocorrelation spectra with the peaks on the diagonals (Reproduced by permission of Academic Press from M. H. Sherwood, D. W. Alderman, and D. M. Grant, *J. Magn. Reson.*, 1989, **84**, 466)

mounted. The armature contains seven accurately drilled holes which define seven rotation axes in the sample frame. A stationary plate attached to the NMR probe contains five axle bearing holes which define five rotation axes in the laboratory frame. The mechanism is assembled by inserting an axle through one of the bearings in the stationary plate

and into one of the holes in the armature. By selecting the appropriate combination of bearing and armature hole, each of the 15 possible flips can be performed. The angle of rotation is limited by a precise system of stops. One advantage of this mechanism is that the axis of the tube containing the sample changes by only 19.5° over all assemblies of the mechanism, so that a reasonably good filling factor can be achieved in the rf solenoid.

Although the pyramidal set of directions was used in the original demonstration of multiple axis 2D chemical shift tensor correlation spectroscopy, it should be realized that any set of six directions would suffice if when substituted into equation (15) they yield a system of linearly independent equations for the six chemical shifts. This restriction eliminates any set of directions that completely lie either in a plane or on the surface of a cone.

An important question that arises is how sensitive is the determination of a tensor given a particular set of measurement directions. To address this question, a variance-like figure of merit was developed¹⁸ which quantifies the sensitivity of a given set of measurement directions. This figure of merit was evaluated for a variety of sets of measurement directions including the pyramidal set and the orthogonal rotation set. The most sensitive set of directions was found to be the six apolar directions defined by the vertices of an icosahedron. For this geometry, the figure of merit represents a significant decrease by a factor of 1.0/1.8 from that of the pyramidal directions. Therefore, it is worth considering the icosahedral direction set when designing future mechanisms. It should be noted that there is no further increase in sensitivity upon including more measurement directions than the six icosahedral directions. Another interesting result of this analysis is that the figure of merit for the orthogonal rotations set is only 1.2 times greater than that for the icosahedral directions set. This indicates that the sensitivity of the tensor measurements made using the traditional rotation method is nearly optimal.

The high symmetry of the icosahedron makes possible a very simple mechanism which rotates the crystal about a single laboratory axis inclined at an angle of 64.4° from the field. As can be seen in Figure 8, it will still be necessary to employ three rotation axes in the sample frame as specified by the three vertices labeled a, b, and c. Unfortunately the sample tube axis will reorient by 68.3° in this new mechanism, and a sacrifice in filling factor may be necessary when implementing this geometry.

Figure 8 Icosahedra showing the vertex directions which can be aligned along the magnetic field by rotating around the a vertex (a), the b vertex (b), and the c vertex (c) (Reproduced by permission of Academic Press from D. W. Alderman, M. H. Sherwood, and D. M. Grant, *J. Magn. Reson.*, 1990, **86**, 60)

6 ASSIGNMENT TECHNIQUES

Before chemical shift tensors can be rationalized in terms of molecular structure, they must first be assigned to their respective nuclei in the unit cell. This can be a challenging step in the interpretation of the results, since the number of possible assignment permutations increases rapidly for larger molecules. The problem is compounded by the fact that most organic crystals contain two or more magnetically nonequivalent molecules in the unit cell. In order fully to exploit the power of the techniques described above, systematic methods of assignment have been developed based on local symmetry and dipolar spectroscopy. These methods have been described in detail in the literature and therefore will only be described qualitatively here.

Nearly all of the chemical shift tensor assignments made to date are based on the assumption that the symmetry elements of the representation ellipsoid should closely coincide with the actual or approximate local symmetry of its assigned nuclear site. For example, it is well established that the δ_{33} principal values of the ^{13}C chemical shift tensors orient perpendicular to the molecular plane in polycyclic aromatic hydrocarbons.¹⁹ This fact is widely used to assign tensors to a particular molecule when there is more than one molecule in the unit cell. In more complicated molecules lacking any molecular symmetry, the approximate local symmetry established by the directly bonded atoms can be used to make assignments. For small molecules this procedure consists of manually comparing principal axis directions of the measured tensors with the approximate local symmetry elements determined from diffraction data until a reasonable match is found. As the number of measured tensors increases, it becomes more difficult to make all possible comparisons and their qualitative nature makes it difficult to distinguish between closely related assignments. In order to quantify such comparisons, the concept of a distance between two tensors was developed.¹⁰ This distance concept has been combined with linear modeling in order to make possible an automated assignment technique which can explore all possible assignments of a reasonably large set of measured tensors to a corresponding set of chemically similar but magnetically nonequivalent nuclear sites.^{10, 20}

The orientational dependence of dipolar interactions has also been exploited in order to assign chemical shift tensors to specific nuclei in single crystal samples. Assignments made in this way are quite reliable since dipolar couplings can be calculated with a high degree of accuracy from the positions of the nuclei alone without resorting to molecular electronic theory. In many organic molecular crystals, the positions of all of the carbon and hydrogen nuclei in the unit cell are known from neutron diffraction studies and thus ^{13}C – ^1H separated local field experiments^{21, 22} can be used in solving the assignment problem.

A simple extension of 2D chemical shift tensor correlation spectroscopy yields a 3D technique which allows detection of ^{13}C – ^1H dipolar couplings for each of the magnetically nonequivalent sets of carbons in the sample.²⁰ The response of each spin is separated according to its chemical shifts at two different magnetic field orientations and a dipolar spectrum is displayed in the third dimension. This is accomplished by inserting a dipolar evolution period between the end of the mixing time and the beginning of the detection period of the previously described 2D experiment.

1 INTRODUCTION

The geometric phase of a quantum system is that portion of its total phase that is independent of the details of the system's temporal evolution. Thus, consider a quantum system prepared in an eigenstate $|\phi\rangle$ with energy E . The evolution of this system is just the familiar $\exp(-iEt/\hbar)|\phi\rangle$. The phase of the eigenstate, $-Et/\hbar$, is purely dynamic because it depends on the length of time t for which the system has evolved. It turns out, perhaps surprisingly, that in systems with sufficiently complex geometry there is an additional contribution to the total phase that is independent of time, but that does depend on the shape of the space through which the system evolves. This component of phase is thus termed geometric. As we illustrate below, even as simple a system as a spin in a moving magnetic field can acquire a geometric phase. Nevertheless, the existence of this effect was largely overlooked until Berry's seminal paper,¹ with some notable exceptions.^{2,3} The history of the geometric phase has been outlined by Berry.⁴ Since the publication of Berry's initial paper,¹ a wealth of primary and secondary literature has appeared (see, for example, Shapere and Wilczek⁵ and Zwanziger et al.,⁶ and references therein).

The geometric phase is a general phenomenon, and has been shown to be significant in a wide range of applications.^{5,6} The exquisite control that magnetic resonance experiments can achieve has proven crucial in providing unambiguous tests of its existence and geometric properties.⁷⁻¹⁰ Moreover, its description has stimulated a new way of thinking about a variety of NMR experiments that has led to the prediction of new phenomena.⁸⁻¹¹ Below we will briefly outline both the general theory of geometric phases, and NMR experiments that have verified the theory.

2 THE GEOMETRY OF QUANTUM EVOLUTION

2.1 The Aharonov–Anandan Phase

The geometric treatment of the general case of quantum evolution is due to Aharonov and Anandan,¹² and we follow their discussion here. Consider, for simplicity, a two-level system, assumed to be in a pure state. The state is completely characterized by its density operator $\hat{\rho}$, which is Hermitian ($\hat{\rho}^\dagger = \hat{\rho}$), idempotent ($\hat{\rho}^2 = \hat{\rho}$), and normalized such that it

has unit trace. The set of all such operators spans a two-dimensional space that has the geometry of a sphere. The evolution of the two-level system can be viewed as a path on this sphere. We associate a wavefunction $|\psi\rangle$ with each density operator in this space, through $\hat{\rho} = |\psi\rangle\langle\psi|$; in fact, we can associate an infinite set of wavefunctions with each $\hat{\rho}$, since the overall phase of the wavefunction is irrelevant. Now suppose that the system is prepared initially in the state $|\psi(0)\rangle$, and that the system evolves along some closed path in the space of density operators during a time T . The system must return to its initial state, up to a phase, as shown in equation (1).

$$|\psi(T)\rangle = e^{i\alpha}|\psi(0)\rangle \quad (1)$$

In general, the phase α includes contributions from both the dynamic and geometric phases. Using $|\psi\rangle$, we define the ket $|\tilde{\psi}\rangle$ through equation (2).

$$|\tilde{\psi}(t)\rangle = e^{-i\phi(t)}|\psi(t)\rangle \quad (2)$$

Here ϕ is determined by the condition in equation (3)

$$\phi(T) - \phi(0) = \alpha \quad (3)$$

The reason for making this definition is that we have obtained a ket such that $|\tilde{\psi}(T)\rangle = |\tilde{\psi}(0)\rangle$. The original state $|\psi(t)\rangle$ obeys the Schrödinger equation

$$i\hbar \frac{d|\psi(t)\rangle}{dt} = \hat{\mathcal{H}}(t)|\psi(t)\rangle \quad (4)$$

where $\hat{\mathcal{H}}(t)$ is the Hamiltonian of the system. By substituting the definition of $|\tilde{\psi}\rangle$ into equation (4), a differential equation for $\phi(t)$ can be obtained:

$$-\frac{d\phi(t)}{dt} = \frac{1}{\hbar} \langle\psi(t)|\hat{\mathcal{H}}(t)|\psi(t)\rangle - \langle\tilde{\psi}(t)|i\frac{d}{dt}|\tilde{\psi}(t)\rangle \quad (5)$$

Integrating equation (5) shows that the total phase acquired by the system can be expressed in two parts. One part is dynamic, in the sense of depending in detail on the Hamiltonian, and is given in equation (6).

$$\alpha_D = \frac{1}{\hbar} \int_0^T \langle\psi(t)|\hat{\mathcal{H}}(t)|\psi(t)\rangle dt \quad (6)$$

The other portion of the phase is given in equation (7).

$$\gamma = \int_0^T \langle\tilde{\psi}(t)|i\frac{d}{dt}|\tilde{\psi}(t)\rangle dt \quad (7)$$

The phase γ is independent of the Hamiltonian, and in fact depends only on the path through the space of $\hat{\rho}$, and not at all on the mechanism that forces the system to traverse that particular path. Note that γ depends on $|\tilde{\psi}(t)\rangle$, not $|\psi(t)\rangle$. The functions $|\tilde{\psi}(t)\rangle$ were explicitly constructed to be free of phase factors, and so we can be sure that a phase generated by integrating the form $i\langle\tilde{\psi}(t)|d/dt|\tilde{\psi}(t)\rangle$ is free of trivial (in the present context) contributions from energy factors and so forth.

Having derived a component of the overall phase of the system that depends only on the geometry and not the Hamiltonian, we can ask under what conditions this term is nonzero. Of particular interest is equation (7), evaluated along a closed loop in the space of density operators. Recognizing that the time t merely parameterizes the path (call the path C), we can rewrite the integral in terms of the path itself, as shown in equation (8).

$$\gamma(C) = i \oint_C \langle \tilde{\psi} | d | \tilde{\psi} \rangle \quad (8)$$

The phase $\gamma(C)$ is often called the Aharonov–Anandan phase (AA phase). Now at any given point on the path one could pick kets such that the integrand of equation (8) is zero there (this is probably why the geometric phase was overlooked for so long). But what is important is the integral around a finite path; it turns out that for spaces that are curved, such as spheres, or spaces with holes, such as the punctured plane, it is impossible to pick kets for which the integrand is *globally* zero. Then $\gamma(C)$ is, in general, nonzero. In NMR the experimentally relevant case is a spherical geometry, this being the shape of the space of density operators of a two-level system. The phase $\gamma(C)$ can be evaluated exactly in this case, yielding the beautifully compact formula shown in equation (9).

$$\gamma(C) = m\Omega(C) \quad (9)$$

Here m is the magnetic quantum number of the state being propagated, and $\Omega(C)$ is the solid angle subtended at the origin of the sphere by the path C . Examples of the geometric phase for different paths are shown in Figure 1.

2.2 The Adiabatic Limit: The Berry Phase

The AA phase described above arises from the geometry of the space of density operators; its generality is due to its independence of the details of the Hamiltonian associated with a given system. The discovery of the AA phase was actually preceded by the discovery by Berry of a geometric phase associated with adiabatic evolution;¹ this so-called Berry phase is a special case of the AA phase. The Berry phase arises from the geometry of the set of Hamiltonians associated with the slowly changing system; we sketch its derivation in this section.

Figure 1 Paths in the space of density operators of a two-level system. The solid angle subtended at the origin is $2\pi(1 - \cos \theta)$ for the cone, θ for the triangle, and 2θ for the slice. (Reproduced by permission of the American Physical Society, from D. Suter, K. T. Mueller, and A. Pines, *Phys. Rev. Lett.*, 1988, **60**, 1218)

The calculation of the Berry phase begins by considering a Hamiltonian that depends on some set of parameters $\mathbf{R}$; for any given set $\mathbf{R}$ we solve the associated Schrödinger equation to find the energies and states of the system, conventionally indexed by the quantum number n , as shown in equation (10).

$$\hat{\mathcal{H}}(\mathbf{R})|n(\mathbf{R})\rangle = E_n(\mathbf{R})|n(\mathbf{R})\rangle \quad (10)$$

The time dependence of the problem is due to the time dependence of the parameters. If the Hamiltonian that drives the system varies slowly in time, compared with the natural precession period of the system, then the evolution can be accurately described in the adiabatic approximation.¹³ In the adiabatic approximation, the state of the system at time t is

$$|\psi(t)\rangle = e^{i\gamma} e^{-i \int_0^t E_n[\mathbf{R}(t')] dt' / \hbar} |n[\mathbf{R}(t)]\rangle \quad (11)$$

Here it is assumed that $|\psi(0)\rangle = |n[\mathbf{R}(0)]\rangle$. A differential equation for the phase γ can be obtained by using $|\psi(t)\rangle$ in the time-dependent Schrödinger equation, and acting with $\langle n(\mathbf{R})|$ on the left. The (integrated) result is summarized in equations (12) and (13).

$$\gamma = i \int_0^T \langle n(\mathbf{R}) | \frac{d}{dt} | n(\mathbf{R}) \rangle dt \quad (12)$$

$$= i \oint_C \langle n(\mathbf{R}) | \nabla_{\mathbf{R}} | n(\mathbf{R}) \rangle d\mathbf{R} \quad (13)$$

This phase is a special case of equation (8) above; we need merely to identify $|n(\mathbf{R})\rangle$ in the present case with $|\tilde{\psi}\rangle$. The natural interpretation is slightly different between the two cases; whereas we interpret the AA phase as arising from the geometry of the space of density operators, the Berry phase, equation (13), arises from the geometry of the parameter space as determined by the set $\mathbf{R}$.

A simple example of a nonzero Berry phase arises for a spin- J particle in a magnetic field of constant magnitude and time-dependent direction. The parameter space $\mathbf{R}$, here just the three components of the magnetic field, has again the geometry of a sphere. If the rate of change of the direction of the field is small compared with the precession rate of the spin around the field, then the adiabatic treatment outlined above holds, and we can expect the Berry phase shown in equation (14).

$$\gamma_n(C) = n\Omega(C) \quad (14)$$

This result is analogous to equation (9) above. This example appears in Berry's original paper,¹ and in more detail in the book by Bohm;¹⁴ a rotating frame analog has been studied experimentally by Suter et al., and equation (14) verified.¹⁵

Although the Berry phase is a special case of the AA phase, more applications in NMR have made use of it, probably because the language describing it is somewhat more familiar. As noted above, whereas the AA phase arises from paths in density operator space, the Berry phase is best viewed as arising from the path followed by the Hamiltonian itself, or, more to the point, of the quantization axis of the system. A slowly varying quantization axis should always be suspected of giving rise to a Berry phase, which in many cases of interest is fairly simple to compute. The simplicity arises from the spherical geometry of the standard parameter space. For the

AA phase, however, while the two-level system yields a simple result, generalization to even a three-level system becomes significantly more complex.¹⁶ The experimental examples of these phases to be discussed below also highlight the subtly different ways they affect real measurements.

3 EXPERIMENTAL CONSEQUENCES OF GEOMETRIC PHASES

3.1 Measurement of the Aharonov–Anandan Phase

A thorough investigation of the phase $\gamma(C)$ [equation (8)] has been carried out by Suter, Mueller, and Pines.⁷ The primary obstacle that any experimental study of such a phase must overcome is that global phases associated with the density operator of an *isolated* system are in principle immeasurable. To see this, recall the invariance of $\hat{\rho}$ to phase changes; the density operator conveys all the information about the system, and the global phase is irrelevant. To measure the phase it is necessary to couple the system to its environment; since this is precisely what is done in any experiment, we see that phase shifts, even of density operators, can be expected to be important not only in theory but in practice as well.

The maximum amount of information about the phase of a system coupled to an environment is provided by an interferometric experiment, and this was the strategy pursued by Suter et al.⁷ Using an approach similar to that employed by Vaughan and colleagues in a study of spinor behavior,¹⁷ a pair of levels in a three-level system was used to provide the two-level density operator to be manipulated. Coherence to the third level provided the phase reference.

Call the phase reference level one and the two-level subsystem levels two and three. The experiment proceeds by applying a selective $\pi/2$ pulse to the 1–2 transition, producing coherence. A time τ later a π pulse is applied to these levels, which will generate an echo. The phase of this echo provides the phase reference; it also has the advantage of refocusing all the dynamic evolution during the time τ . In a second experiment, during the refocusing period pulses are applied to the 2–3 subsystem to drive the associated density operator through a cycle such as those shown in Figure 1. Because this subsystem has a level in common with the 1–2 transition, the phase of the refocused 1–2 coherence is sensitive to the phase of the 2–3 state. In the work of Suter et al.,⁷ this sequence was carried out for a variety of paths C of the 2–3 subsystem, and the phase of the 1–2 echo measured. The predicted phase shifts of these experiments are $\frac{1}{2}\Omega(C)$ [see equation (9)]; the experimental results and the theory are given in Figure 2. These results show that the phase $\gamma(C)$ does indeed depend on the solid angle in the way predicted; this experiment represents a complete and thorough test of the geometric evolution predicted in equation (8).

3.2 Measurement of the Berry Phase

Because any adiabatic reorientation of the quantization axis of a system can yield a geometric phase, there are a number of examples from NMR of this kind of geometric evolution. The most commonly occurring case is in solid state NMR at

Figure 2 Experimentally determined values of $\gamma(C)$ as a function of solid angle $\Omega(C)$. The paths used are those shown in Figure 1. The solid line is theory [equation 9]. (Reproduced by permission of the American Physical Society, from D. Suter, K. T. Mueller, and A. Pines, *Phys. Rev. Lett.*, 1988, **60**, 1218)

intermediate to low fields, where the spin degrees of freedom of the nuclei are not completely decoupled from the spatial degrees of freedom. In such a case, sample reorientations (for example, rotation) yield a slowly changing quantization axis, and hence a geometric phase.^{8,9,11} The experiment of Tycko⁸ is a particularly vivid example of this behavior.

Tycko performed a pure nuclear quadrupole resonance (NQR) experiment on the ^{35}Cl nuclei in a rotating single crystal of sodium chlorate (NaClO_3). In this material the quadrupolar interaction is dominant for the chlorine spins, yielding a transition frequency (in zero field) of some 30 MHz. The quantization axis for the chlorine is determined by the quadrupole principal axis system (PAS). By placing a single crystal of NaClO_3 in the tuned NQR detection coil, with the crystal c axis collinear with the coil axis, all four chlorine nuclei in the unit cell have equivalent orientations because the principal axis of each is at an angle of 54.74° with respect to the coil axis, and the quadrupolar interaction is axially symmetric ($\eta = 0$). Such an orientation, like any other, gives a single sharp NQR line. When the sample is made to rotate, however, the spectrum changes qualitatively. Rotating around the crystal c axis preserves the equivalence of the chlorine nuclei in the unit cell, but now the quantization axis of each one is time-dependent, tracing a circle around the coil axis (Figure 3).

Each spin state $|n\rangle$ acquires a geometric phase γ_n [see equation (13)] at a constant rate, and since the coupled partners in observable transitions ($|\frac{3}{2}\rangle \leftrightarrow |\frac{1}{2}\rangle$ and $|\frac{1}{2}\rangle \leftrightarrow |-\frac{1}{2}\rangle$) pick up different phases, shifts of the resonance lines are observed in the spectrum. There is a subtlety in defining the spin states due to their degeneracy in zero field;^{8,18,19} suffice it to say that the $|\pm\frac{3}{2}\rangle$ pair are unmixed by the rotation, and so yield good basis states, and that the superposition of the $|\pm\frac{1}{2}\rangle$ states with mixing angle $\arctan(2 \tan \theta)$, with θ being the angle between the quadrupole PAS and the coil axis, form good basis states. These states can be used in equation (13) to calculate the phase shift. The phase differences, modulo 2π , for the observable transitions are 0 and $\pm 2\sqrt{3}\pi$, which translate, in the frequency

Figure 3 The experimental arrangement used in the pure NQR experiment of Tycko. The crystal c axis of NaClO_3 is oriented along the coil axis; the sample can be rotated around this axis. (Reproduced by permission of the American Physical Society, from R. Tycko, *Phys. Rev. Lett.*, 1987, **58**, 2281)

domain, into shifts at 0 and $\pm\sqrt{3}\omega_R/2\pi$ Hz (with $\omega_R/2\pi$ the rotation frequency). Note the difference between this result and the usual spinning sidebands of high field solid state NMR: here there are always four lines of constant relative intensity (two are degenerate at zero frequency shift) for all rotation speeds, and the splittings are irrationally related to the rotation frequency. Spectra, at different rotation frequencies, are shown in Figure 4. This very clean result clearly demonstrates the Berry phase, and also illustrates the primary regime in which geometric phases are important in NMR: intermediate to low field experiments, in which the quantization axis is time-dependent.

4 SUMMARY

While geometric methods have been important in relativistic quantum mechanics for some time, it is only recently that they have become used in the nonrelativistic case. The geometric phases discussed here are concrete realizations of the importance of geometry in even simple systems such as spins in magnetic fields. NMR has played a major role in demonstrating their properties, and in turn, geometric approaches are providing new insights and new predictive power into the design of magnetic resonance experiments.

1 INTRODUCTION

Beginning in 1988, a number of developments have taken place in the design of NMR pulse sequences suitable for reintroducing homonuclear dipole–dipole couplings to magic angle spinning (MAS) experiments. These sequences utilize the direct coupling between nuclear magnetic dipoles to measure internuclear distances, thereby providing important constraints for the determination of molecular structure.¹ The motivation for utilizing solid state NMR stems from its ability to access polycrystalline and amorphous systems, including those with high molecular mass. Often, these systems are not amenable to study by crystallography or multidimensional solution NMR. The NMR methods described here offer resolution comparable with X-ray crystallography (0.005 to 0.02 nm for distances of ≤ 0.5 nm) and have been employed to investigate the structure of biomolecules and polymeric materials.^{2,3}

In relatively rare circumstances, internuclear distance measurements can be made directly from well-resolved splittings in powder spectra.⁴ A more common situation is for the shielding anisotropy and the multiplicity of homonuclear and heteronuclear couplings to obscure the splittings associated with coupled spins. It is therefore necessary to improve the spectral resolution using MAS, which attenuates these interactions, and to reintroduce the homonuclear dipolar couplings using a selectively engineered pulse sequence. Until quite recently, few MAS recoupling experiments had been proposed, in part due to the complexity of the theoretical analysis, which requires consideration of the time-dependent spin interactions during MAS. The complications arise because of the noncommutation of the flip-flop term of the homonuclear dipolar Hamiltonian with the chemical shift interactions.

This article describes several homonuclear MAS recoupling schemes. Rotational resonance (R^2)^{5,6} relies on the mechanical motion of the sample rotor to recouple the spin system, while dipolar recovery at the magic angle (DRAMA),^{7,8} unified spin echo and magic echo (USEME),^{9,10} simple excitation for the dephasing of rotational echo amplitudes (SEDRA),¹¹ and rf-driven recoupling (RFDR),^{12,13} employ multiple pulse

sequences to interfere with the spatial averaging imposed by MAS. The coupled spin systems which are currently addressed with these schemes are comprised of ‘magnetically dilute’ spin- $\frac{1}{2}$ pairs, such as ^{13}C – ^{13}C , ^{15}N – ^{15}N , or ^{31}P – ^{31}P . Typical ^{13}C dipolar strengths are ~ 2 kHz for directly bonded spin pairs, and decrease to < 50 Hz for distances ~ 0.4 to 0.6 nm, which are of interest in structural problems. Owing to the small magnitude of these couplings, and also due to the low natural abundance of some nuclei (e.g. 1.1% for ^{13}C and 0.33% for ^{15}N), samples are prepared with selective or uniform labeling, and dipolar couplings are measured within the high-resolution environment afforded by MAS.

2 DIPOLAR HAMILTONIAN UNDER MAGIC ANGLE SPINNING

The dipolar Hamiltonian describes the coupling of nuclear magnetic moments in a high magnetic field, and can be expressed in the general form

$$\mathcal{H}_D(t) = \sum_{i < j} \omega_{ij}^D(t) [3I_{zi}I_{zj} - \mathbf{I}_i \cdot \mathbf{I}_j] \quad (1)$$

Equation (1) is composed of two parts, the bilinear ‘A’ term, $2I_{zi}I_{zj}$, and the flip-flop ‘B’ term $-\frac{1}{2}[I_{-1}I_{+2} + I_{+1}I_{-2}]$. The coefficients, $\omega_{ij}^D(t)$, are directly proportional to the magnitude of the dipole–dipole interaction between nuclei i and j according to equation (2), where r_{ij} is the internuclear distance, γ_i and γ_j are the gyromagnetic ratios of the two nuclei, and $\theta_{ij}(t)$ is the time-dependent angle between the static magnetic field and the internuclear vector:

$$\omega_{ij}^D(t) = \frac{\mu_0}{4\pi} \frac{\gamma_i \gamma_j}{r_{ij}^3} \left(\frac{1 - 3 \cos^2 \theta_{ij}(t)}{2} \right) \quad (2)$$

When the rotor axis is oriented at the magic angle, all terms of equation (2) become time-dependent.

For ‘unlike’ spins (i.e. possessing different γ s), the flip-flop term in equation (1) is truncated, and the heteronuclear dipolar Hamiltonian reduces to the ‘A’ contribution. For ‘like’ spins, the flip-flop term is usually truncated when the difference in isotropic chemical shifts, $\Delta\omega = \omega_1 - \omega_2$, between the spins is relatively large compared with the dipole coupling, and the resulting Hamiltonian is similar to the heteronuclear case. This situation is frequently encountered for ^{13}C and ^{15}N spins. For ^1H pairs, the more common situation is $|\mathcal{H}_D| \gg \Delta\omega$, and both terms in equation (1) are significant.

MAS imparts a time dependence to the chemical shift and dipolar coupling terms in the Hamiltonian. The chemical shift Hamiltonian ($\mathcal{H}_{CS}$) consists of a time-independent isotropic contribution and oscillating terms due to the shielding anisotropy, and it is efficiently averaged by MAS even if the rotation frequency, ω_r , is less than the magnitude of $|\mathcal{H}_{CS}|$, resulting in sharp spectral lines. The consequent MAS spectrum is comprised of a centerband at ω_i , flanked by a set of rotational sidebands spaced at integer multiples of ω_r . The ‘inhomogeneous’ dynamics of $\mathcal{H}_{CS}$ arises from the fact that it is self-commuting at different times.¹⁴ The heteronuclear coupling term is also inhomogeneous, and dipolar terms between weakly coupled spins are strongly attenuated at typical

MAS spinning speeds (3–12 kHz). In contrast, the homonuclear dipolar coupling behaves homogeneously in that sharp sidebands are not formed unless the rotation rate exceeds the coupling strength, $\omega_r \gg |\mathcal{H}_D|$. Under most conditions, the chemical shift difference also leads to truncation of the flip-flop term.

3 ROTOR-DRIVEN HOMONUCLEAR RECOUPLING

For homonuclear spin pairs, the energy mismatch created by the isotropic chemical shift difference limits the efficiency of magnetization exchange via the dipolar flip-flop term. An exception occurs when the sample rotation frequency satisfies the rotational resonance (R^2) condition, $\Delta\omega = n\omega_r$, where n is a small integer.¹⁵ At R^2 , the macroscopic sample spinning frequency matches the energy difference between two chemically shifted spins, and the dipolar flip-flop term again becomes significant. The reintroduction of the dipolar coupling permits energy to exchange between the spins at an enhanced rate which is governed by the coupling strength, and furthermore, induces spectral line broadening and splittings that are particularly prominent for strongly coupled spins.

In 1988, Raleigh et al. rediscovered the R^2 phenomenon and recognized that it could be exploited to measure weak homonuclear couplings.^{5,6} The basis of this technique is a careful matching of spinning rate to the chemical shift difference ($\Delta\omega = n\omega_r$) and the detection of magnetization exchange between spin pairs. Figure 1 shows the pulse sequence used for measuring the distance between two chemically shifted spins I_{z1} and I_{z2} . A nonequilibrium population is established by inverting one of the resonance lines, and longitudinal exchange of the magnetization between coupled spins occurs during the mixing time, τ_m . The free induction decay signal is recorded for a number of discrete mixing times, and a plot of the difference polarization $\frac{1}{2}(I_{z1} - I_{z2})$ is compared with a numerical simulation of the exchange for the estimated dipolar coupling strength.

Figure 1 The R^2 pulse sequence. Initial transverse magnetization, generated with cross polarization, is placed along the z axis using a $\pi/2$ pulse. A population imbalance is created by inverting one resonance peak using a weak, selective pulse or DANTE sequence. Rotor-driven magnetization exchange takes place between coupled spins if the sample spinning rate is adjusted to match the difference in isotropic chemical shifts ($\Delta\omega_{\text{iso}} = n\omega_r$). After a variable mixing period, τ_m , a second ($\pi/2$) pulse returns the magnetization to the transverse plane and the remaining difference in signal intensities, $\frac{1}{2}(I_{z1} - I_{z2})$, is recorded as a free induction decay signal. A magnetization exchange curve is generated by recording this quantity for a number of discrete mixing times, usually between 0–30 ms. Strong proton decoupling reduces dephasing by abundant protons and helps to maintain a sharp R^2 condition

Figure 2 (a) Experimental (●) and simulated (—) magnetization exchange curve for double- ^{13}C -labeled zinc acetate $\text{Zn}^{2+}(\text{CH}_3\text{COO}^-)_2 \cdot 2\text{H}_2\text{O}$ recorded at the $n = 3R^2$ condition ($\omega_r/2\pi = 4.38$ kHz). Experimental points represent the difference magnetization $\frac{1}{2}(I_{z1} - I_{z2})$ normalized to $\tau_m = 0$. (b) The magnetization exchange curve recorded at $\omega_r/2\pi = 4.26$ kHz, corresponding to an off- R^2 condition. Simulation parameters for zinc acetate are found in Levitt et al.⁶

A demonstration of magnetization exchange at the $n = 3$ condition is shown in Figure 2(a) for 1,2- ^{13}C -labeled zinc acetate $\text{Zn}^{2+}(\text{CH}_3\text{COO}^-)_2 \cdot 2\text{H}_2\text{O}$, where oscillatory decay of the difference magnetization arises from exchange between these strongly coupled spins. A numerical simulation of the magnetization curve is also shown and corresponds to an internuclear distance of 0.151 ± 0.002 nm. Figure 2(b) shows the difference polarization recorded at a sample rotation rate which is set 120 Hz away from the $n = 3R^2$ condition. Model compound studies have demonstrated that internuclear distances ≤ 0.6 nm to a resolution of ± 0.005 to ± 0.02 nm are accessible via the R^2 method.

The theoretical aspects of magnetization exchange at the R^2 condition are treated in a number of works using Average Hamiltonian theory^{6,16,17} and Floquet theory.^{17–19} A fictitious field approach, wherein magnetization exchange is described within a $\{|2\rangle, |3\rangle\}$ subspace, provides a geometric description of resonant magnetization exchange.^{6,13} The Floquet analysis leads to an expression for the effective Hamiltonian at sample rotation rates close to the R^2 condition $\Delta\omega \approx n\omega_r$ and which is valid for synchronous acquisition of the data:

$$\begin{aligned} \bar{\mathcal{H}}_{\text{eff}} = & \frac{1}{2}(\Delta\omega - n\omega_r)[I_{z1} - I_{z2}] \\ & + \frac{1}{2}|\omega_{\text{eff}}^D(n)|[I_{+1}I_{-2} + I_{-1}I_{+2}] \end{aligned} \quad (3)$$

The first term in equation (3) represents the offset from the R^2 condition. In general, the effective dipolar frequency $|\omega_{\text{eff}}^D(N)|$ appearing in the second term depends on both the coupling and the shielding anisotropies. However, in the case of small shielding anisotropy, it reduces to the magnitude of the n th Fourier coefficient $|\omega_n^D(\alpha, \beta)|$ of the time-dependent prefactor in equation (3), where (α, β) denote the orientation of the internuclear vector in a frame rotating with the rotor.

The exact time course of magnetization exchange at R^2 is determined by the magnitude of the homonuclear dipolar coupling, the principal values of the I_{z1} and I_{z2} chemical shift tensors, the relative orientations of the chemical shift and dipolar tensors, and the isotropic J coupling of the spin pair. Magnetization exchange rates are insensitive to molecular orientations for the $n = 1$ condition for a typical application, but have a stronger dependence for higher resonance orders.²⁰ In some circumstances, this sensitivity can be exploited to yield additional structural information, in the form of tensor orientations, from MAS spectra.

The R^2 analysis also requires an estimation of the zero quantum relaxation time, T_2^{ZQ} which is associated with the zero quantum coherence ($I_{x1}I_{y2} - I_{y1}I_{x2}$). Kubo and McDowell have shown that it can be approximated by the individual single quantum relaxation rates, T_2 .¹⁹ An estimate of $(T_2^{ZQ})^{-1}$ is therefore found by summing the inverse linewidths of resonance peaks (measured at an off- R^2 condition) after correction for magnet inhomogeneity. The zero quantum relaxation pathway competes with magnetization exchange at R^2 and is most significant when couplings are weak or resonance peaks are broad. Under these circumstances, the exchange processes is damped, and the magnetization exchange decays monotonically.

The R^2 technique has been applied to a variety of biological solid state systems. Examples include the investigation of the mechanism of inactivation in a ^{31}P -labeled enzyme bound inhibitor,²¹ establishing the folding motif of membrane-bound peptides,²² measuring retinal-to-protein distances in the 26 kDa integral membrane protein bacteriorhodopsin,^{23,24} and describing the amide bond geometry of a fragment of the β -amyloid protein associated with Alzheimer's disease.²⁵

4 HOMONUCLEAR RECOUPLING VIA SPIN ECHOES

RFDR (rf-driven dipolar recoupling) and SEDRA (simple excitation for the dephasing of rotational echo amplitudes) are two related approaches employing spin echoes to reintroduce homonuclear dipolar couplings to MAS spectra. In both experiments, recoupling is accomplished via the modulation of the dipolar Hamiltonian by the difference in chemical shifts between the coupled spins. Both schemes lead to an efficient reintroduction of the homonuclear dipolar interaction across a broad range of chemical shift differences and MAS spinning speeds.

The SEDRA experiment is based on the observation of transverse echo dephasing during a rotor-synchronized π pulse train. Dephasing due to shielding anisotropy and heteronuclear interactions is refocused after each pair of spin echo π pulses, while a net dephasing arises from the homonuclear dipolar flip-flop term. A train of rotor-synchronized π pulses is also used

Figure 3 The RFDR pulse scheme for 2D homonuclear correlation spectroscopy. Following cross polarization to create transverse S spin magnetization (shown here for ^{13}C), spins evolve according to their chemical shifts during t_1 . A nonselective $\pi/2$ pulse places the magnetization of one spin along the z axis. During a variable mixing time, τ_m , single π pulses (one per rotor period, τ_r) drive longitudinal magnetization exchange between coupled spins. A second nonselective $\pi/2$ pulse returns the magnetization to the transverse plane and S spin magnetization is recorded. The SEDRA sequence involves monitoring the dephasing with the same MAS spin echo sequence. Reprinted from Bennett et al.¹²

for RFDR, but the exchange of longitudinal magnetization among dipolar coupled spins is detected instead. Figure 3 shows a diagram of the RFDR pulse sequence. In the one-dimensional (1D) version, an inversion pulse is employed, and magnetization exchange between coupled spins is reported by the time course of the difference polarization. A 2D version of the experiment utilizes a t_1 evolution period, and the resulting chemical shift correlation spectra show cross peaks between dipole coupled sites.

The spin dynamics of the spin echo recoupling sequence can be approximated with average Hamiltonian theory¹² or Floquet theory.¹¹ The zeroth order result (neglecting shielding anisotropy) for a spin echo cycle of one π pulse per rotor period is an effective Hamiltonian containing only a dipolar flip-flop term:

$$\tilde{\mathcal{H}}_{\text{eff}}^{(0)} = \frac{1}{2} \bar{\omega}_{\text{eff}}^D [I_{+1}I_{-2} + I_{+2}I_{-1}] \quad (4)$$

The dipolar frequency, $\bar{\omega}_{\text{eff}}^D$ depends on the spinning speed ω_r and $\Delta\omega$ as follows:

$$\bar{\omega}_{\text{eff}}^D = \frac{2}{\pi} \sum_{n=1,2} \text{Re} \{ \omega_n^D(\alpha, \beta) \} \frac{\frac{\Delta\omega}{\omega_r}}{\left(\frac{\Delta\omega}{\omega_r} \right)^2 - n^2} \times (-1)^{n-1} \sin \left(n\pi \frac{\Delta\omega}{\omega_r} \right) \quad (5)$$

The dipolar frequency has maxima at the rotational resonance conditions, but significant recoupling is achieved over a broader range. The pulse sequence is particularly effective in recoupling under the condition $\omega_r \leq \Delta\omega \leq 2\omega_r$.

Simulation of the magnetization exchange during RFDR (monitored by 2D cross-peak intensities or 1D exchange curves) and dephasing during SEDRA experiments requires the measurement or reasonable estimation of relaxation parameters, and all relevant chemical shift and dipolar tensors parameters and orientations, as in the case of R^2 .

Figure 4 A stack plot of the 2D RFDR magnitude spectrum of uniformly ^{13}C -labeled alanine recorded with $\tau_m = 8.6$ ms and $\omega_r/2\pi = 3.72$ kHz. Cross peaks demonstrate the dipolar coupled spins. In this example, cross peaks from directly bonded ^{13}C nuclei appear in ≤ 2 ms. Reprinted from Bennett et al.¹²

SEDRA and RFDR are ‘broadband’ recoupling schemes that offer some important advantages over the R^2 technique in situations where spectral lines are inhomogeneously broadened, or when it is not feasible to match the rotation rate dictated by the R^2 condition. The RFDR technique and the recently introduced t -SEDRA experiment²⁶, are suitable for 2D homonuclear dipolar correlation spectroscopy, and may be used to map couplings between more than two coupled spins, if the exchange of magnetization between all coupled spins is traced. A demonstration of the 2D RFDR correlation experiment is given in Figure 4, for uniformly ^{13}C -labeled alanine, where cross peaks between all coupled ^{13}C sites are prominent after a mixing time of 8.6 ms. A similar 2D approach was adopted to examine the geometry of two conformers in the membrane protein bacteriorhodopsin.²⁷

5 DIRECT RECOUPLING SEQUENCES: DRAMA AND USEME

A direct reintroduction of the homonuclear coupling is accomplished with rotor synchronized $\pi/2$ pulses in the DRAMA (dipolar recovery at the magic angle) experiment. This scheme, shown in Figure 5, relies on the interference between the RF modulation of the dipolar spin operators and the oscillations imposed on them by MAS. Chemical shift interactions are removed to zeroth order through the use of π pulses. The recoupling effect in DRAMA does not require the existence of chemical shift differences between the spins. However, it is most efficient when the chemical shift anisotropies and resonance offsets are small compared with ω_r since these interactions complicate the spin dynamics and lead to a loss of magnetization.

The effective Hamiltonian can be obtained with Floquet theory²⁸ or average Hamiltonian theory.^{7,8} The latter analysis, equation (6) yields a nonzero dipolar term:

$$\bar{H}_{\text{eff}}^{(0)} = \frac{4}{\pi} \text{Re} \{ \omega_{n=1}^D(\alpha, \beta) \} \bar{\omega}_{\text{eff}}^D (I_{z1}I_{z2} - I_{y1}I_{y2}) \quad (6)$$

DRAMA has also been extended to include double quantum filtering, which restricts the detected NMR signal to resonances from coupled spin pairs and therefore simplifies the spectra of

Figure 5 The DRAMA pulse sequence. The pulse cycle, consisting of 4 τ_r is comprised of a pair of $\pi/2$ pulses with alternating phase X , $\bar{X}$, and two π pulses which are also alternated by X , $\bar{X}$. The $\pi/2$ pulses interfere with dipolar refocussing by MAS

complex molecules.⁸ This approach has been used to enhance selectively the signal of ^{13}C sites within a ~ 0.5 nm radius of a selectively labeled site in an undecapeptide of molecular mass 1100.

Direct recoupling of the dipolar interaction is also achieved with a continuous rf field applied during the second half of each rotor cycle. This approach, called USEME (unified spin echo and magic echo) utilizes the partial cancellation of rotational echo refocussing via a combined spin echo and magic echo sequence to yields a scaled homonuclear coupling.^{9,10}

6 EMERGING TECHNIQUES

Improvements in the efficiency of homonuclear recoupling schemes remains an important goal. Several recently introduced homonuclear recoupling sequences hold the promise of compensating for the complications introduced by large chemical shift differences in DRAMA-type experiments.^{29,30} The MELODRAMA (melding of spin locking and DRAMA) method reintroduces the dipolar coupling in a spin-locking interaction frame by utilizing 90° rotor-synchronized phase shifts.³¹ The recoupling effect is relatively insensitive to chemical shift and anisotropy, rendering the method suitable for 2D correlation spectroscopy. The double quantum filtering experiment called HORROR (homonuclear rotary resonance), utilizes a rotary resonance condition between the sample rotation frequency and the rf field to provide efficient double quantum transfer between coupled spin pairs.³² A novel approach to homonuclear recoupling that combines angle switching and phase shifted π and $\pi/2$ pulses was recently reported by Tycko.³³ This experiment, called NASDY (normal angle spinning dipolar spectroscopy) takes advantage of the static contribution to the dipolar coupling by recovering this contribution at a sample rotation angle other than the magic angle.

7 CONCLUDING REMARKS

Solid state NMR experiments that restore dipolar couplings to MAS spectra are becoming increasingly important for investigating the molecular structure of polycrystalline and amorphous materials. These experiments provide geometric information by measuring precise distance measurements and establishing spatial connectivities. Selectivity is also offered

through the choice of nucleus and specific labeling scheme. Potential applications include distinguishing between various protein folding patterns, determining the bonding arrangements of molecules absorbed on surfaces, mapping the interface between two materials or phases such as polymer blends, and elucidating active site geometries in biomolecules.

A number of important challenges remain in the development of homonuclear recoupling schemes; these include improvements in sensitivity for the detection of weak couplings and extension of these methods to multiple spin environments in a manner analogous to multidimensional solution NMR. Such developments will vastly improve the efficiency of gathering structural information via solid state NMR.

1 BACKGROUND AND PHENOMENOLOGY

In condensed matter, dipolar interactions among nuclear magnetic moments and their manipulation in multiple quantum (MQ) NMR experiments induce multiple spin correlations. The temporal and spatial development of these collective modes yield information about the structure and the dynamics of spin networks.¹⁻³ In this article, we examine the fundamental aspects of the growth of multiple spin/multiple quantum coherences in extended dipolar coupled spin networks driven by rf magnetic fields.

In MQ NMR, investigations of strongly dipolar coupled spin systems, such as rigid solids, the simplest relevant Hamiltonian needed to describe and understand experimental observations in a laboratory reference frame is given by

$$\hat{\mathcal{H}}(t) = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_d + \hat{\mathcal{H}}_{\text{rf}}(t) \quad (1)$$

The contributions to $\hat{\mathcal{H}}(t)$ in equation (1) include the interactions of the nuclear magnetic moments with a strong static magnetic field ($\hat{\mathcal{H}}_Z$), with other nuclear magnetic moments through dipolar interactions ($\hat{\mathcal{H}}_d$), and with time-dependent rf magnetic fields ($\hat{\mathcal{H}}_{\text{rf}}$). Furthermore, $[\hat{\mathcal{H}}_Z, \hat{\mathcal{H}}_d] = 0$, and $[\hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_d, \hat{\mathcal{H}}_{\text{rf}}] \neq 0$.

In order to simplify the description and make connection with experiments, the Hamiltonian of equation (1) is transformed to a frame rotating about the z axis of the laboratory frame at the nuclear spin precession frequency. In this new reference frame, $\hat{\mathcal{H}}_Z$ disappears. A further transformation to

another noninertial frame, the rf toggling frame which ‘follows’ the directions of the rf fields during a pulse sequence, produces an effective Hamiltonian $\hat{\mathcal{H}}_{\text{de}}(t)$. In this newest frame, $\hat{\mathcal{H}}_{\text{de}}(t)$ results from the modulation of $\hat{\mathcal{H}}_d$ by the time-dependent rf fields. The time average of $\hat{\mathcal{H}}_{\text{de}}(t)$ over the period of a cycle of a multiple pulse excitation sequence yields, under appropriate conditions, a time-independent average Hamiltonian $\hat{\mathcal{H}}_d$:

$$\hat{\mathcal{H}}_d = \sum_{j,k} D_{jk} f(\hat{\mathbf{I}}_j, \hat{\mathbf{I}}_k) \quad (2)$$

where D_{jk} is a dipolar coupling constant between spins j and k

$$D_{jk} = \frac{\gamma^2 \hbar^2 (3 \cos^2 \theta_{jk} - 1)}{2r_{jk}^3} \quad (3)$$

and $f(\hat{\mathbf{I}}_j, \hat{\mathbf{I}}_k)$ is a function of bilinear operators involving the components of the spin angular momentum operators $\hat{\mathbf{I}}$, of spins j and k .

Formally, the geometrical interpretations of these transformations correspond to unitary transformations on the state of the spin system (i.e. the density operator) and its dynamical variables (i.e. the spin angular momentum and Hamiltonian operators). The resulting interaction pictures associate different parts of the time dependence of the physical system [i.e. the spins in the sample evolving under the Hamiltonian in equation (1)] to the state of the system and to the dynamical variables. This procedure is generic to all NMR experiments involving the manipulation of spin Hamiltonians. By a judicious choice of a reference frame, different portions of the Hamiltonian can be selected to appear to dominate the spin dynamics; hence, the possibility to discriminate among the various contributions in a spin Hamiltonian. Such an approach underlies the success of NMR spectroscopy. It is noteworthy that these transformations, from one frame to another, inertial or noninertial, do not necessarily preserve the invariance and conservation principles of physics. For example, spin energies measured in the laboratory frame are different from those measured in the rotating frame, while the spin quantum numbers, $I = \frac{1}{2}$ for protons, remain identical. However, observations restricted within a reference frame will be consistent with known laws of physics.

In pulsed NMR experiments, the evolution of the spin system is detected in the rotating frame. The time development of the spin system under $\hat{\mathcal{H}}_d$ in the toggling frame is monitored directly, in multiple pulse line-narrowing sequences such as MREV-8, or indirectly, in MQ NMR, by stroboscopic observations when both the rotating and the toggling frames coincide.

A variety of rf multiple pulse sequences have been tailored to produce different average dipolar Hamiltonians $\hat{\mathcal{H}}_d$. In MQ NMR experiments,¹⁻³ $[\hat{\mathcal{H}}_Z, \hat{\mathcal{H}}_d] \neq 0$. The spin portions [see equation (2)] $f(\hat{\mathbf{I}}_j, \hat{\mathbf{I}}_k)$ of these nonsecular average dipolar Hamiltonians include, among the bilinear spin operators, terms like $\hat{I}_{jz}\hat{I}_{k\pm}$, and $\hat{I}_{j\pm}\hat{I}_{k\pm}$, where $\hat{I}_+$ and $\hat{I}_-$ correspond to the raising and lowering (or ladder) spin angular momentum operators, respectively. These operators in $\hat{\mathcal{H}}_d$ are responsible for the radiative coupling of Zeeman nuclear spin states with differing magnetic quantum numbers M_z by ± 1 and ± 2 .

Evolution under $\bar{H}_d$ for extended periods of time leads to nonstationary states with possibly larger differences in ΔM_z , as discussed in the next section. MQ NMR pulse excitation sequences for solids are specifically designed and optimized to generate multiple spin/multiple quantum coherences among the spins in a macroscopic sample.

The selection rules for the observation of transverse magnetization, or single spin/single quantum coherences, correspond to transitions with $\Delta M_z = \pm 1$. Thus, the creation and evolution of coherent superpositions of quantum states with $\Delta M_z \neq 1$ cannot be detected directly. Indirect piecewise mappings of multiple spin/multiple quantum coherences are accomplished through two-dimensional NMR methods as a function of the excitation and/or evolution times.¹⁻³ MQ NMR spectra obtained in this fashion reveal the presence of multiple spin/multiple quantum coherences with $\Delta M_z = n$, where n is the order of the coherences, in the sample during the excitation/evolution period (see Figure 1).

Figure 1 shows schematic MQ NMR spectra, obtained with time-resolved two-dimensional experiments, as a function of the excitation time. For a fixed excitation period, the spectral intensities decrease with increasing orders. With increasing excitation times, a redistribution of spectral intensities is observed to proceed or to 'flow' towards higher order coherences.

Understanding the behavior of the MQ NMR spectral intensity profiles of solids, as a function of order and excitation time, still poses an interesting challenge to NMR spectroscopists. Specifically, one would like to learn how the multiple spin dynamics depend on the lattice parameters and the space-filling properties of spin networks. Examples of the latter include spatial extent, morphologies, and effective dimensionalities of domain structures on mesoscopic length scales, i.e. in

the range 1 nm to 1 μ m, in condensed matter systems. More generally, the recognition of emergent properties, generic or universal behavior, amidst the complexities of this many-body problem with multiple scales, would deepen our understanding of the fundamental aspects of MQ NMR. These issues are addressed in the following sections, from the perspective of statistical mechanics.

2 ENSEMBLE CONSIDERATIONS

From a macroscopic point of view, in a MQ NMR experiment energy is pumped through rf magnetic fields produced by electronic devices into a solid sample residing in a strong static magnetic field. From a microscopic point of view, this injection of energy proceeds from individual nuclear magnetic moments, embedded in the lattice, to induce multiple spin correlations. Both the microscopic and macroscopic descriptions of the rf irradiation processes involve nonequilibrium driven systems: the macroscopic solid and the microscopic magnetic moments. As these experiments are performed in laboratories on a macroscopic scale, but interpreted microscopically, it is imperative to understand clearly how the macroscopic observables emerge from the numerous microscopic degrees of freedom.

A rigid solid is an aggregate of a large number of spatially fixed atoms. Various solids exist due to the nature of their constituents, which include atoms, ions, or molecules. In MQ NMR of rigid solids, ions and molecules lose their distinct identities on account of the through-space dipolar interactions among all magnetic moments. Hence, the spin network, consisting of the nuclear magnetic moments and their dipolar coupling constants, remains the only relevant and essential substratum onto which the microscopic degrees of freedom, the multiple spin coherences, evolve in MQ NMR experiments.

Solid samples used in MQ NMR investigations typically contain on the order of 10^{20} or more spins. The multiple spin correlations induced in spin networks by present-day MQ NMR methodologies involve coherences with up to possibly 10^2 spins. Consequently, the size difference between the sample and the multiple spin coherences suggests that the macroscopic observables, or responses, in MQ NMR experiments, arise from the random superposition of numerous multiple spin coherences. In other words, the sample could be viewed as an ensemble of loosely coupled subsystems.

Such a description of a macroscopic sample is certainly valid in liquid state NMR experiments, where under normal conditions, molecules behave as essentially independent subsystems. This outlook can also be extended to correlated molecular systems, as observed in critical fluctuations close to critical points.⁴ For example, close to a consolute temperature, the intermolecular interactions among molecules in a critical binary fluid contrive and lead to composition fluctuations over length and timescales that can be quite large compared with those associated with the molecules, but still much smaller than those of the macroscopic sample. However, care must be exercised with such an analogy, since in critical phenomena systems are at equilibrium, while MQ NMR has to do with nonequilibrium driven systems. Possibly a more appropriate comparison for MQ NMR would be with the growth kinetics and processes of domain structures observed during phase

Figure 1 Typical MQ NMR spectra of a rigid solid: spectral intensities $I(n, t)$ as a function of order n and excitation time t , with $t_1 < t_2 < t_3$

Figure 2 A macroscopic sample viewed as an ensemble of loosely coupled N -spin subsystems. Relevant length scales include: the lattice spacing a , the correlation length of a multiple spin coherence ξ , the extent of a subsystem l , and the sample size L , which satisfy $a < \xi < l \ll L$. Spins are denoted by $\bullet$. An 11-spin coherence is also shown, with the lines representing the dipolar coupling constants appearing in the product, which multiplies the corresponding product operator term of the density operator

separation of binary fluids.⁵ In this case, a similarity to critical phenomena exists; however, a richer behavior arises due to the nonequilibrium conditions and nonlinearity. In any event, the point at issue, that a macroscopic sample can be viewed, under certain conditions, as an ensemble of loosely coupled subsystems, where a subsystem can be one or several molecules, or even part of a spin network in a solid, would appear physically plausible.

Figure 2 shows a representation of a macroscopic sample as a statistical ensemble of N -spin subsystems. The number of spins N per subsystem is much smaller, by many orders of magnitude, than the total number of spins in the sample. The relevant length scales in this ensemble include the sample size L , the spatial extent of a subsystem l , the correlation length of the multiple spin coherences ξ , and the underlying lattice spacing a . This hierarchy of length scales satisfy the inequalities, $a < \xi < l \ll L$. Interaction energies between subsystems are assumed to be weak in comparison with interaction energies within the subsystems. This amounts to a neglect of surface effects for the MQ dynamics. Such approximation becomes more accurate in the limit when $\xi \ll l$. These effects are nevertheless necessary to achieve equilibrium or uniform spin temperature in the ensemble. The presence of the long-range dipolar interactions among the magnetic moments would appear to preclude or even invalidate this perspective of the sample as representing an ensemble of loosely coupled subsystems. However, as will be seen in Section 5, in time-resolved MQ NMR experiments, multiple spin coherences are ‘weighted’ by products of dipolar coupling constants. As it turns out, in spin networks, the distributions of dipolar coupling constants and their products are extremely wide. Since, at early excitation times, the MQ spin dynamics are dominated by the largest coupling constants and their products, the ensemble picture remains a good approximation for most experimental conditions. This approximation breaks down for mean field interpretations, e.g. MQ NMR experiments having infinite excitation periods.

Measurements performed over a short period of time on a macroscopic sample, made up of an ensemble of subsystems, correspond to averaging over the ensemble.⁷ When a physical property of a macroscopic system is equal to this property averaged over the subsystems, spatial ergodicity exists. In statistical mechanics, the Gibbs canonical ensemble is composed of identical systems from the macroscopic point

of view, i.e. they all have the same number of particles N , volume V , and temperature T . However, most systems are in different microscopic states. In the ensemble construction for a nonequilibrium driven macroscopic system, as described above, none of the subsystems need to be strictly identical. Instead, one assumes that statistical homogeneity is valid for the subsystems. On a subsystem scale, the statistical properties are stationary in space, i.e. a subsystem is statistically translationally invariant in space. Another feature of time-resolved MQ NMR measurements on such an ensemble, is the fact that, as the multiple spin coherences grow, so does their correlation length ξ . As the inequality $\xi < l$ must be satisfied for a consistent interpretation of the ensemble, this implies that the number of subsystems actually decreases as a function of time. This should be of no significant consequence, as long as $l \ll L$. Under present MQ NMR experimental conditions, these conditions are always satisfied, and the ensembles will consist of huge numbers of subsystems. Such ensembles yield asymptotic statistical states in experimental investigations.

Thus, a time-resolved MQ NMR measurement on a macroscopic solid is assumed to be equivalent to many independent measurements on the subsystems. Since the decomposition of the macroscopic sample into subsystems is not unique, the averaging process over the ensemble implied in a measurement is really a summation over the subsystems. As the spin dynamics are being probed on the scale of a subsystem, the response of the collective ensemble is taken to reflect the behavior of a typical subsystem. Underlying the spin dynamics are dipolar coupling constants and their products. Due to subtleties related to wide distributions and to averaging over products, the role of the couplings is more intricate than appears in the present discussion. For example, the distinction between average and typical behavior is very important in the MQ NMR of large spin networks.⁶ We shall return to these issues in Section 6.

3 QUANTUM MECHANICS OF AN N -SPIN SUBSYSTEM

The focus on the spin dynamics within a subsystem and the subsequent averaging over a large collection of subsystems, yields a more tractable avenue to the understanding of

MQ NMR of solids, rather than treating a single spin system consisting of 10^{20} or more spins. Nevertheless, on the timescale of MQ NMR experiments, the spin dynamics within a subsystem still retain some of complexities of the many-body problem.

In a subsystem consisting of N spins I , there are $(2I + 1)^N$ stationary states of $\hat{\mathcal{H}}_Z$. For $I = \frac{1}{2}$, these 2^N energy levels can be classified according to the magnetic quantum numbers M_z given by

$$M_z = \sum_i^N m_{iz} \quad (4)$$

where m_{iz} is the eigenvalue ($m_z = \pm \frac{1}{2}$) of the i th spin. These Zeeman states, in the magnetic field $\mathbf{B}_0$, have corresponding energies

$$E_z = -\gamma \hbar B_0 M_z \quad (5)$$

and degeneracies

$$\Omega = \frac{N!}{(\frac{1}{2}N + M_z)!(\frac{1}{2}N - M_z)!} \quad (6)$$

The Zeeman manifolds are further broadened by homonuclear dipolar perturbations $\hat{\mathcal{H}}_d$. The resulting energy level diagram can be characterized, in principle, by the combined eigenvalues and eigenfunctions of $\hat{\mathcal{H}}_Z$ and $\hat{\mathcal{H}}_d$. However, due to the presence of bilinear spin operators in $\hat{\mathcal{H}}_d$, the combined eigenfunctions are constructed from direct products of $\hat{\mathcal{H}}_Z$ eigenfunctions. As a consequence, the m_{iz} eigenvalues are not good quantum numbers. In addition, the presence of large N rapidly makes this approach analytically intractable.

Therefore, as a first approximation, only the energy level diagram due to $\hat{\mathcal{H}}_Z$ is considered. This is justifiable, since the Zeeman splittings are usually of the order of tens to hundreds of megahertz as compared with tens of kilohertz for dipolar splittings. Radiative coupling of pairs of Zeeman levels leads to

$$\binom{2^N}{2} = 2^N(2^N - 1)/2 \quad (7)$$

possible transitions. The distinction between $+n$ and $-n$ coherences results in $2^N(2^N - 1)$ transitions. These transitions, or coherences, are classified according to their orders n . The number of coherences of order $n \neq 0$, Z_n , where $|n| \leq N$, is obtained from the constrained sum over the products of degeneracies of coupled Zeeman manifolds,

$$Z_n = \sum_{M_i - M_j = n} \binom{N}{\frac{1}{2}N + M_i} \binom{N}{\frac{1}{2}N + M_j} = \binom{2N}{N - n} \quad (8)$$

The number of coherences within a Zeeman manifold or with $n = 0$, Z_0 , is given by

$$\begin{aligned} Z_0 &= \sum_{M_i = N/2+1}^{-N/2+1} \binom{N}{\frac{1}{2}N + M_i} \left[\binom{N}{\frac{1}{2}N + M_i} - 1 \right] \\ &= \binom{2N}{N} - 2^N \end{aligned} \quad (9)$$

Radiative coupling within a subsystem of N dipolar coupled spins $\frac{1}{2}$ can be rationalized, to a very good degree of approximation, on the basis of the possible $2^N(2^N - 1)$ transitions which connect the 2^N energy levels. The information content needed to describe this physical situation involves $2^N(2^N - 1)$ coherences and 2^N populations, or a total of 4^N parameters.

The 2^N eigenfunctions of $\hat{\mathcal{H}}_Z$, $|r\rangle$, for an N -spin- $\frac{1}{2}$ subsystem, constitute a complete basis set to characterize any spectroscopic experiments involving coherences and populations. As a consequence, any state $|\psi\rangle$ of a subsystem, can be expanded with the complete Zeeman basis set,

$$|\psi\rangle = \sum_{r=1}^{2^N} |r\rangle \langle r|\psi\rangle = \sum_{r=1}^{2^N} c_r |r\rangle \quad (10)$$

$$\langle r|\psi\rangle = c_r \quad (11)$$

Similarly, the observables or expectation values corresponding to any dynamical variables, such as the magnetization M_x , detected in a spectroscopic measurement on a subsystem, can be represented in this basis set with the corresponding operator $\hat{M}_x$ as,

$$\begin{aligned} \langle \psi|\hat{M}_x|\psi\rangle &= \sum_{r,s} \langle \psi|s\rangle \langle s|\hat{M}_x|r\rangle \langle r|\psi\rangle \\ &= \sum_{r,s} c_s^* c_r \langle s|\hat{M}_x|r\rangle \end{aligned} \quad (12)$$

where $c_r = \langle r|\psi\rangle$. The matrix elements $\langle s|\hat{M}_x|r\rangle$ are numbers related to the values of the dynamical variable M_x . The matrix elements, $c_s^* c_r$, are numbers describing the state $|\psi\rangle$ of the subsystem; there are 4^N such matrix elements. As a consequence, this matrix is isomorphic to, or has the same information content as, the description in terms of coherences and populations.^{8,9} The diagonal elements are proportional to the probabilities of occupation of the energy levels, and consequently to the populations. The off-diagonal elements correspond to correlations between the values of the coefficients c_r . For time-dependent problems, as in spectroscopic measurements, these off-diagonal elements are related to coherent superpositions of the stationary states, i.e. coherences or transitions, present in a spin subsystem.

Different states $|\psi\rangle$ yield different values for the same observable, as can be seen from equation (12). The products, $c_s^* c_r$, vary according to the states $|\psi\rangle$, while the matrix elements $\langle s|\hat{M}_x|r\rangle$ remain invariant. It proves convenient to describe the state of the subsystem, with a projection operator for a single state, $\hat{P}_\psi = |\psi\rangle\langle\psi|$, in the Zeeman basis set:

$$\langle r|\hat{P}_\psi|s\rangle = c_s^* c_r \quad (13)$$

With this projection operator, the expectation value of $\hat{M}_x$ in a subsystem becomes [see equation (12)]:

$$\begin{aligned} \langle \hat{M}_x \rangle &= \langle \psi|\hat{M}_x|\psi\rangle = \sum_{r,s} \langle r|\hat{P}_\psi|s\rangle \langle s|\hat{M}_x|r\rangle \\ &= \text{Tr}\{\hat{P}_\psi \hat{M}_x\} \end{aligned} \quad (14)$$

4 QUANTUM STATISTICAL MECHANICS OF AN ENSEMBLE OF N -SPIN SUBSYSTEMS

A measurement of M_x over an ensemble of subsystems is equivalent to averaging over $\langle \hat{M}_x \rangle$ in equation (14). As the state $|\psi\rangle$ or $c_{s,r}^*$ of each subsystem will generally be different, while the dynamical variable will be identical, the averaging gives

$$\overline{\langle \hat{M}_x \rangle} = \sum_{r,s} \overline{\langle r | \hat{P}_\psi | s \rangle \langle s | \hat{M}_x | r \rangle} = \text{Tr}\{\hat{\rho} \hat{M}_x\} \quad (15)$$

with $\hat{\rho}$, the density matrix of the ensemble,^{8,9} defined as

$$\langle r | \hat{\rho} | s \rangle = \sum_{\psi} p_{\psi} \langle r | \hat{P}_{\psi} | s \rangle = \overline{\langle r | \hat{P}_{\psi} | s \rangle} = \overline{c_{s,r}^* c_r} \quad (16)$$

where p_{ψ} is the statistical weight of $|\psi\rangle$ in the ensemble.

For NMR experiments, the density matrix is represented by a density operator, corresponding to the Boltzmann weight of the canonical ensemble with the appropriate Hamiltonian operator defined with respect to some convenient reference frame,

$$\hat{\rho} = Q^{-1} e^{-\hat{\mathcal{H}}/kT} \quad (17)$$

where Q is the ensemble partition function,

$$Q = \sum_{r=1}^{2^N} \langle r | e^{-\hat{\mathcal{H}}/kT} | r \rangle \quad (18)$$

The description of any spectroscopic experiment will involve the time dependence, due to evolution under some Hamiltonian $\hat{\mathcal{H}}$ of $\hat{\rho}$ to characterize the ensemble, or $\hat{P}$ to represent a subsystem. In the Schrödinger picture, the time dependence is assigned to the state of the system, specifically, to the coefficients $c_r(t)$ of equation (11).^{8,9} In MQ NMR experiments of solids, the relevant Hamiltonian corresponds to the time average of $\hat{\mathcal{H}}_d$ in the rf toggling frame, $\hat{\mathcal{H}}_d$ [see equation (2)], over a cycle of the rf excitation sequence. The equation of motion for $\hat{P}$ is obtained by inserting $|\psi\rangle$ into the time-dependent Schrödinger equation to yield^{8,9}

$$\frac{d\hat{P}}{dt} = \frac{i}{\hbar} [\hat{P}, \hat{\mathcal{H}}_d] \quad (19)$$

The averaging of equation (19) over the ensemble of subsystems with identical $\hat{\mathcal{H}}_d$ gives the equation of motion for $\hat{\rho}$:

$$\frac{d\hat{\rho}}{dt} = \frac{i}{\hbar} [\hat{\rho}, \hat{\mathcal{H}}_d] \quad (20)$$

Equation (20) is also known as the Liouville–von Neumann equation.

For a time independent average Hamiltonian, a formal solution to equation (20) is

$$\hat{\rho}(t) = \hat{U} \hat{\rho}(0) \hat{U}^{-1} \quad (21)$$

where the propagator $\hat{U}$ is defined as

$$\hat{U} = \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}}_d t\right) \quad (22)$$

The interpretation of equation (21) is of importance for understanding the development of multiple spin coherences in time resolved MQ NMR experiments. Insight in this many-body problem, as discussed in the next section, can be gained through a Taylor expansion of $\hat{\rho}(t)$ about $t = 0$:

$$\hat{\rho}(t) = \hat{\rho}(0) + \sum_{n=1}^{\infty} \frac{t^n}{n!} \frac{d^n}{dt^n} \hat{\rho}(t) \Big|_{t=0} \quad (23)$$

From equations (21) and (22), one finds the derivatives of $\hat{\rho}(t)$, of which only the first two are given here:

$$\frac{d\hat{\rho}(t)}{dt} = \frac{i}{\hbar} [\hat{\rho}(0), \hat{\mathcal{H}}_d] \quad (24)$$

$$\frac{d^2 \hat{\rho}(t)}{dt^2} = -\frac{1}{\hbar} [[\hat{\rho}(0), \hat{\mathcal{H}}_d], \hat{\mathcal{H}}_d] \quad (25)$$

Finally, by substituting equations (24) and (25) and all the other derivatives into equation (23), one obtains:

$$\begin{aligned} \hat{\rho}(t) = & \hat{\rho}(0) + \frac{it}{\hbar} [\hat{\rho}(0), \hat{\mathcal{H}}_d] \\ & - \frac{t^2}{2\hbar^2} [[\hat{\rho}(0), \hat{\mathcal{H}}_d], \hat{\mathcal{H}}_d] + \dots \end{aligned} \quad (26)$$

5 DEVELOPMENT OF MULTIPLE SPIN/MULTIPLE QUANTUM COHERENCES IN DIPOLAR COUPLED SOLIDS

The power series in time for $\hat{\rho}(t)$ in equation (26) describes the evolution of the spin dynamics in MQ NMR experiments. With the initial conditions corresponding to the spin system at equilibrium in a strong Zeeman field at a high temperature, equation (17) implies

$$\hat{\rho}(0) \propto \hat{I}_z = \sum_i \hat{I}_{zi} \quad (27)$$

As pointed out in Section 3, since $|\hat{\mathcal{H}}_Z| \gg |\hat{\mathcal{H}}_d|$, it is appropriate to neglect the contributions of $\hat{\mathcal{H}}_d$ in the initial conditions. However, in the toggling reference frame, $\hat{\mathcal{H}}_d$ is crucial for determining the evolution of the spin dynamics. By inserting $\hat{\rho}(0)$ and the nonsecular average Hamiltonian $\hat{\mathcal{H}}_d$ suitable for a particular MQ NMR experiment into equation (26), it is possible to examine the qualitative features of the growth of multiple spin/multiple quantum coherences in a solid.

With $\rho(0)$ corresponding to single-spin interactions and $\hat{\mathcal{H}}_d$ to two-spin interactions, the ascending terms in the expansion of $\hat{\rho}(t)$ describe the sequential growth of multiple spin coherences due to the evolution under $\hat{\mathcal{H}}_d$. In the first-order terms t^1 , the commutators produces two-spin correlations of the form $\hat{I}_{i\alpha} \hat{I}_{j\beta}$, where the components α and β of the spin angular momentum operators are determined by the actual

details of $\hat{\mathcal{H}}_d$. The nested commutators in the second-order terms t^2 yield three-spin operators, $\hat{I}_{i\alpha}\hat{I}_{j\beta}\hat{I}_{k\gamma}$. The hierarchy of nested commutators from the higher order terms t^n generate $(n - 1)$ -spin operators. By introducing ladder (raising and lowering) operators in these product operators, the order n of the corresponding MQCs becomes explicit; the sum of raising operators minus the sum of the lowering operators in a product operator gives the order of the coherence. Thus, to observe an n quantum coherence it is necessary to have, at the minimum, a contribution of order t^{n+1} , implying the presence of an n -spin/ n quantum operator in the expansion of $\hat{\rho}(t)$. Higher order terms can also produce n quantum coherences. The distinction between these different n quantum coherences comes from the number of spins participating in the correlations. Since multiple spin coherences contribute to equation (26) through the product of dipolar coupling constants (as discussed below and in Section 6), the lattice parameters r_{ij} and θ_{ij} will ultimately control and distinguish between the various n quantum coherences.

The interplay between the development of multiple spin coherences and the order of the resulting multiple quantum coherences depends on selection rules associated with the nature of $\hat{\mathcal{H}}_d$ and equation (26). With respect to the time development of the number of spins in multiple spin coherences, the bilinear spin operators of $\hat{\mathcal{H}}_d$ and the algebra of the nested commutators in equation (26) imply a cascade process in the growth of correlations. An n -spin coherence can only grow by sequentially incorporating one single spin at a time, one after another. The time development of multiple quantum coherences is constrained to pathways, in a K -spin/ n quantum space, which depend uniquely on the nature of $\hat{\mathcal{H}}_d$.^{2,10} The pulse excitation sequences for MQ NMR of solids produce generic classes of $\hat{\mathcal{H}}_d$ terms: 2-spin/0,2 quantum operators, 2-spin/1-quantum operators, and 2-spin/2 quantum operators. These excitation sequences achieve a redistribution of MQ NMR spectral intensities according to selections rules on ΔK and Δn . For example, with 2-spin/2 quantum operators in $\hat{\mathcal{H}}_d$, and an $\hat{I}_z$ initial condition, equation (26) and the selection rules $\Delta K = \pm 1$ and $\Delta n = \pm 2$, demonstrate that only even coherences develop; in addition, the evolution cannot generate 4-spin/4 quantum coherences. The redistribution of spectral intensities produced by the different $\hat{\mathcal{H}}_d$ terms is optimized according to the size or spatial distribution of the spins within a subsystem, e.g. for the detection of spin clusters, or extended spin networks.

One of the simplest models, the so-called statistical or Gaussian model,¹ used to interpret MQ NMR spectra of solids, consists of assuming that all the individual coherences possible in an N -spin subsystem have the same magnitudes with random phases, and that all have been excited at long excitation times in the sample or ensemble of subsystems. Time-reversal excitation produces transitions with identical phases within an order.¹¹ Hence, the assumption of a priori equal weight of the different coherences implies that the MQ NMR spectral intensities $I(n,t)$ are proportional to Z_n , [see equation (8)]. Stated differently, the distribution of coherences in the ensemble of subsystems is proportional to Z_n . For large N and small n , it is possible to transform Z_n in equation (8) with Stirling's approximation $y! \approx (2\pi y)^{\frac{1}{2}} y^y e^{-y}$ to give

$$Z_n \approx 4^N (\pi N)^{-\frac{1}{2}} e^{-n^2/N} \quad (28)$$

As a consequence, according to the statistical model, a MQ NMR spectral intensity profile as a function of order $I(n,t)$ should be Gaussian, as suggested by equation (28).

The time dependence of these profiles arises from the growth of the subsystem size $N(t)$. The variance $N(t)$ obtained from fitting $I(n,t)$ to a Gaussian function of n represents the effective number of dynamically coupled spins, in a typical subsystem, following an excitation period of duration t under $\hat{\mathcal{H}}_d$. In addition to spin counting with this variance, it has been suggested that the rate of change in $N(t)$ with time reflects on some of the space-filling properties, such as dimensionality effects, of spin networks.^{1,1,12-14} Qualitatively, three generic classes of behavior have been observed for $N(t)$. Saturation in $N(t)$ implies the presence of isolated clusters of spins. Unbounded growth curves are observed in extended spin networks. Saturation behavior seen at early excitation times, followed by unbounded growth, indicates the occurrence of coupled clusters of spins.

The simplicity of the statistical model accounts for its widespread use in the MQ NMR literature of solids.^{2,3} However, some questions have been raised concerning the validity of the assumption of the a priori equal weight of all coherences.^{2,6} In addition, the convenience of the Gaussian model with the use of simple fitting procedures to analyze MQ NMR spectral intensity profiles is not successful with extended spin networks.¹⁵ To appreciate the nature of these problems, and to understand the development of multiple spin/multiple quantum coherences in solids beyond the level of the statistical model, it is necessary to consider further fundamental aspects of the spin dynamics in MQ NMR.

As discussed in previous sections, the interpretation of MQ NMR experiments of solids relies on the spin dynamics within a subsystem, followed by averaging over an ensemble of subsystems. The density operator $\hat{\rho}$ in equation (17) and its equation of motion [equation (26)] reflect this two-fold averaging: a quantum mechanical averaging or the determination of expectation values in a subsystem [equation (14)], and a statistical averaging over the expectation values due to the distribution of subsystem states in the ensemble [equations (15) and (16)].

It is possible to construct a statistical ensemble of diagrams or graphs, including evolution, which is completely isomorphic with the density operator formalism used to describe MQ NMR.² This approach provides complementary physical insights into MQ NMR spin dynamics, averaging, and measurements. The diagrams include vertices corresponding to spins, and edges or links to delineate dipolar coupling constants between spins. The weight of an edge is proportional to the absolute value of the dipolar coupling constant. The state of a spin is represented by a color. For a spin $\frac{1}{2}$ there are three colors, $\hat{I}_x$, $\hat{I}_y$, and $\hat{I}_z$; generalization to higher spins is possible.

The decomposition of the density operator proceeds by examining an N -spin subsystem, under rigid lattice conditions and without any symmetry elements. In such an N -spin subsystem, the number of distinct subsets n_i each containing i spins is given by the binomial coefficient:

$$n_i = \binom{N}{i} \quad (29)$$

For example, the number of pairs of spins or dipolar coupling constants in a single subsystem is n_2 . The subsets can range in size from $i = 1$ to N . The sum over all possible subsets is:

$$n_T = \sum_{i=1}^N n_i = \sum_{i=1}^N \binom{N}{i} = 2^N - 1 \quad (30)$$

In equation (30), n_T is the sum of all possible spin correlations in the spin subsystem. By including the states of the spins or colors within the spin correlations, one obtains

$$n_T^c = \sum_{i=1}^N n_i 3^i = \sum_{i=1}^N \binom{N}{i} 3^i = 4^N - 1 \quad (31)$$

where n_T^c is the total number of distinct colored subsets, and is equal to the number of elements (coherences and populations) of the normalized density operator in an N -spin- $\frac{1}{2}$ subsystem.

The growth of multiple spin/multiple quantum coherences is described by equation (26). From the interpretation of this equation, the coherences were seen to grow sequentially by adding one spin after another with increasing time. It is clear that this description is valid for the density operator, either in the product operator formalism or in the ensemble of colored spin correlations described above.

However, there is an essential feature related to the growth processes and the averaging over the subsystems, which becomes more obvious with the diagrams. Consider a generic term of $(n + 1)$ th order in the Taylor expansion of equation (19) for the time dependence of the projection operator $\hat{P}_\psi$. The resulting equation is analogous to equation (26) with $\hat{P}_\psi$ replacing $\hat{\rho}$. The product of spin operators will include n -spin operators corresponding to different spins in the subsystem. As $\hat{\mathcal{H}}_d$ is present in the nested commutators, there will also be products of $(n - 1)$ dipolar coupling constants which multiply the n -spin product operators. For example, a 3-spin coherence involving spins i, j , and k , will have a corresponding product operator of the form $\hat{I}_{i\alpha}\hat{I}_{j\beta}\hat{I}_{k\gamma}$, multiplied by a product of dipolar coupling constants $D_{ij}D_{jk}$. Hence, in general, the contributions or weights of n -spin coherences in the equation of motion are determined by products of $(n - 1)$ dipolar coupling constants. A diagram, consisting of n vertices connected with $(n - 1)$ edges is called a tree; no loops are permitted in such a graph. The number of ways to connect n vertices, with $(n - 1)$ edges chosen among $\binom{n}{2}$ distinct edges, corresponds to the number of distinct trees given by

$$n^{n-2} \quad (32)$$

Equation (32) also gives the number of products of n dipolar coupling constants for a particular n -spin coherence. In an N -spin subsystem, the total number of products of n dipolar coupling constants for n -spin coherences is

$$\binom{N}{n} n^{n-2} \quad (33)$$

The averaging over an ensemble of subsystems, in order to obtain $\hat{\rho}$, as discussed in Section 4 and in NMR texts,^{8,9} proceeds by assuming that the Hamiltonians are identical for all

subsystems [see equations (19) and (20)]. This is certainly true for a hypothetical representative ensemble, or approximately true for a sample viewed as an ensemble of loosely coupled subsystems, as presented in Section 2. However, when the averaging is done over a nonequilibrium ensemble for a finite sample, care must be taken to distinguish between the sum in the Hamiltonian [see equations (2), (19) and (20)] and the realizations of multiple spin correlations (with corresponding product operators) present in the ensemble. As an example, consider a 25-spin subsystem. In this subsystem, there is only a single MQ coherence of order 25 represented by a product operator consisting of 25 raising operators. According to equation (26), the 25-spin/25 quantum coherence is weighted by a product of 24 dipolar coupling constants. Among these spins, there are $\binom{25}{2} = 300$ distinct dipolar coupling constants. The number of distinct products of 24 dipolar coupling constants corresponds to the number of trees, in this case $25^{23} \approx 10^{32}$ realizations. It should be clear that a macroscopic sample consisting of 10^{20} spins will not have enough 25-spin subsystems to represent all trees or possible realizations of the 25-MQ coherence. An MQ NMR measurement on a macroscopic sample, consisting of an ensemble of subsystems, is really an average over the subsystems [see equation (16)]. The average over multiple spin coherences is really performed over the distribution of corresponding trees present in the ensemble, i.e. over products of dipolar coupling constants. To appreciate the intricacies of such a measurement or averaging procedure, we now examine the distributions of dipolar coupling constants and their products in spin networks.

6 STATISTICAL PROPERTIES OF DISTRIBUTIONS OF DIPOLAR COUPLING CONSTANTS AND THEIR PRODUCTS IN LARGE SPIN NETWORKS

Consideration of equation (26) demonstrated that different multiple spin coherences contribute to the evolution of ρ according to the values of the products of dipolar coupling constants. Thus, for a finite excitation time, coherences cannot be treated equally, as is assumed in the Gaussian statistical model.¹ Only in the limit of an infinite excitation time will all the coherences contribute equally to the spin dynamics.⁶ The recognition that in spin networks the distributions of dipolar coupling constants and their products are characterized by asymmetry associated with extreme widths is important for understanding MQ NMR spin dynamics.⁶ Difficulties encountered with the interpretation of equation (26), due to the presence of multiple length- and timescales, actually arise from these broad and peculiar distributions.

In three-dimensional solids, lattice sums of dipolar coupling constants can be replaced by a continuum approximation involving integrals such as

$$\sum_{i,j} D_{ij} \propto \int_r (1/r^3) r^2 dr \propto \ln r \quad (34)$$

For an infinite sample, the lattice sum diverges, while for finite spin networks the sum is conditionally convergent, i.e. it depends on the sample shape. Some approaches, such as the Ewald summation and the Lorentz cavity method, have

been devised to study these distributions in samples of general shapes.

In one-dimensional solids, the lattice sums can be performed analytically. Consider an infinite crystalline one-dimensional chain of spins with lattice parameter r oriented perpendicular to the Zeeman field. The average dipolar coupling constant per spin $\langle D \rangle_s$ is

$$\langle D \rangle_s = 2 \sum_{k=1}^{\infty} \frac{1}{2} \gamma^2 \hbar^2 (kr)^{-3} \approx 1.20 \gamma^2 \hbar^2 / r^3 \quad (35)$$

In this case, 83% of the average is determined by the value of two nearest neighbor couplings out of an infinity of couplings!

Figure 3 shows a schematic distribution of the absolute values of dipolar coupling constants and their logarithms for a large spin subsystem. One should note that the distribution in Figure 3(a) is really a caricature, since in large networks the width essentially cannot be observed on linear scales.⁶ Several statistical features are illustrated by Figure 3. The average $\langle |D| \rangle$ is determined by the coupling constants in the tail of the distribution, while the most probable value $|D|_{MPV}$ is sensitive to the small and numerous long-range couplings. The transformation of the distribution on a logarithmic scale demonstrates the huge dynamic range of the distribution. For example in a two-dimensional square lattice of $10^2 \times 10^2$ spins, the distribution of coupling constants covers over 10 orders of magnitude. Differences between $\langle \ln |D| \rangle$ and $\ln \langle |D| \rangle$ are important to reconcile with measurements on an ensemble. The value of $\langle |D| \rangle$ is sensitive to the largest coupling constants, while $\langle \ln |D| \rangle$ is more sensitive to the details of the overall distribution. Such distinctions are significant in the physics of

Figure 3 (a) Schematic distribution of the absolute values of dipolar coupling constants in an N -spin subsystem. (b) Schematic distribution of the logarithm of the absolute values of dipolar coupling constants in the same subsystem. Note the difference between $\langle \ln |D_{ij}| \rangle$ and $\ln \langle |D_{ij}| \rangle$. The analogous distributions, involving products of dipolar coupling constants, show similar behavior, but with wider distributions

disordered systems.^{16,17} Products of dipolar coupling constants show similar features; however, the distributions are even wider.⁶

Probably the most interesting feature of these distributions arises from the scaling behavior of the statistical properties as a function of N , the number of spins. The relative fluctuations RF,

$$RF = \frac{(\langle |D|^2 \rangle - \langle |D| \rangle^2)^{\frac{1}{2}}}{\langle |D| \rangle} \quad (36)$$

measure the relative spread about the mean. In the limit of large spin networks,

$$RF \propto N^{-\frac{1}{2}} \quad (37)$$

This result implies that the distributions become wider as N increases, i.e. there is no self-averaging. The ratio of the most probable value to the first moment can be shown to scale as $N^{+\frac{3}{2}}$. The product of dipolar coupling constants shows a similar behavior with the same scaling exponents.⁶ Such behavior is highly counterintuitive, since in random additive processes, within the central limit theorem, the relative fluctuations scale as $N^{-\frac{1}{2}}$, and the most probable value coincides with the first moment in the thermodynamic limit.

Some implications of these results for the growth of multiple spin coherences/multiple quantum coherences are beginning to emerge.^{2,18} For example, anisotropy effects in the growth process should be determined by the products of the angular contributions of dipolar coupling constants. In a measurement on an ensemble of subsystems, the realizations of multiple spin coherences which are detected should be those with the largest products of dipolar coupling constants. However, these products are the least numerous but still dominate the dynamics due to their large weights. This last result would suggest that a single subsystem, where a multiple spin coherence with the largest possible product has been excited, could eventually dominate a macroscopic measurement. The statistical properties of the distributions of dipolar coupling constants and their products should also be relevant for other aspects of strongly dipolar coupled spin systems; examples include problems associated with FIDs¹⁹ and the lineshapes,²⁰ spin diffusion,²¹ and spin temperature.²²

7 DYNAMICAL SCALE INVARIANCE IN THE GROWTH OF MULTIPLE SPIN CORRELATIONS IN DIPOLAR COUPLED SOLIDS

Dilation or scaling symmetry, observed under certain conditions in some physical systems, is a generalization of the concept of similarity among geometrical objects. In geometry, the properties of two circles with different radii are similar to one another by simple transformations of scales. In physical sciences, the practical aspects of scaling involve the determination of the relevant scaled variables to describe a phenomenon, such that all data acquired under a range of conditions collapse onto some single universal plot. Thus, scaling reveals an invariance or a kind of unification among the relevant scaled variables, which was not obvious

in the original unscaled variables. Understanding the physical reasons underlying scaling symmetry usually leads to deeper insights into the phenomenon.

Some scaling arguments have been applied to various aspects of the growth of multiple spin/multiple quantum coherences in solids.^{1,2,15,23} In the context of the Gaussian statistical model, studies have focused on the behavior of the variance $N(t)$ in dilution effects¹ and power law growth² in spin networks, and dimensional analysis of growth curves.²³ A more elaborate scaling analysis of MQ NMR spectral intensity profiles, as a function of order and excitation time, demonstrated non-Gaussian behavior in extended spin networks.¹⁵ These studies also provided additional support for the case of exponentially decaying intensity profiles. Behind these approaches lies the belief that the physics of the growth processes should be invariant or scale free, for some range of length- and timescales.

Baum et al.¹ have studied the effects of dilution of spin networks with MQ NMR. With increasing dilution, the growth curves $N(t)$ were shifted to longer excitation times. When the excitation time was multiplied by a scaling factor, all growth curves for the diluted systems could be collapsed onto the data of the undiluted or 'pure' spin network. In this case, the scaling symmetry demonstrates the invariance of the physics of the growth processes in the pure and diluted spin networks. A simple dilution in time relates these different systems. The scaling factor was observed to be a function of dilution; no serious attempts were made to understand this phenomenology.

Lacelle² has studied the growth curves $N(t)$ of a large variety of solid samples. All the data were seen to follow power law behavior,

$$N(t) \propto t^\alpha \quad (38)$$

where α is a growth exponent characteristic of the samples and the growth mechanism. The presence of power law growth indicates a scale invariant process, such that the functional

$$N(\lambda t) = \lambda^\alpha N(t) \quad (39)$$

exists for any values of the scaling factor λ . The solution of equation (39), i.e. equation (38), is obtained by setting $\lambda = 1/t$ in equation (39). In order to determine the physics behind the growth exponents, several models were considered. For example, in diffusive growth, the length scale ξ of the multiple spin correlations should follow

$$\xi \propto t^{1/2} \quad (40)$$

The space-filling properties of a homogeneously embedded solid in D dimensions imply that

$$N \propto \xi^D \quad (41)$$

Equations (40) and (41) yield

$$N \propto t^{D/2} \quad (42)$$

from which the growth exponent $\alpha = D/2$ is deduced for a diffusive growth mechanism. None of the models developed could account successfully for all the observed growth

exponents. However, a classification of the spin networks could be achieved with the long time behavior of the growth rates

$$\frac{dN}{dt} \propto t^{\alpha-1} \quad (43)$$

When $\alpha < 1$, the growth rates converge to zero at long excitation times, implying the presence of clusters of spins. When $\alpha > 1$, a divergence in the growth rates should occur, which indicates the presence of an extended network. The case of $\alpha = 1$ corresponds to the threshold between these regimes. In a sense, α serves as a localization/delocalization criterion for multiple spin coherences.

Scruggs and Gleason²³ have examined the growth curves of different simple crystalline materials. By assuming that the growth processes were only determined by a relevant time-independent scale, the inverse of the square root of the second moment of the dipolar linewidths, the different growth curves collapsed onto a single universal curve for early excitation times. Their assumption for this empirical scaling is implicitly equivalent to assuming that the growth processes are dominated by nearest neighbor couplings, since Van Vleck's second moment is also dominated by such couplings.

One could argue about the quality and the quantitative aspects of the fitting procedures with the Gaussian approximation in these studies.^{1,2,23} However, the value of such studies really lies in the efforts made to explore the possible facets of scaling in the growth processes of multiple spin/multiple quantum coherences. To ascertain any quantitative aspects of scaling, for example, growth exponents, under these circumstances it is clear that many more experiments involving high quality data will be required.

Lacelle et al.¹⁵ have developed some scaling arguments in order to test the validity of the Gaussian statistical model. In particular, they strived to observe the scaling of MQ NMR spectra, as a function of order and excitation times, in extended spin networks. The Gaussian dependence suggested for the spectral intensity profiles $I(n,t)$ in equation (28) is actually a generalized homogeneous equation. With the time dependence of the variance $N(t)$ corresponding to a random walk model in product operator space,^{1,10} the expected scaling, $I(n,t)/t^{-1/2}$ versus $n/t^{1/2}$, should have collapsed all MQ NMR spectra for a sample onto a single universal spectrum. The lack of scaling clearly demonstrated non-Gaussian behavior. Instead, consideration of the multiplicative nature of the coupling constants associated with product operators in equation (26) led to a heuristic argument predicting exponential decaying intensity profiles. The ensuing scaling analysis collapsed MQ NMR spectra, obtained at different excitation times, onto a single universal spectrum, thereby demonstrating dynamical scale invariance in the growth process of multiple spin/multiple quantum coherences. Such an approach reveals some aspects of the complexities, richness, and subtleness of multiple spin dynamics in MQ NMR of solids.

1 INTRODUCTION

Polymorphism is ubiquitous in solid state chemistry, commonly occurring for a very wide range of materials. Polymorphs are different solid forms (usually crystalline) of a given compound. The differences lie in solid state structure, i.e. in the spatial arrangement of the atoms or molecules. They may be relatively minor (e.g. variations in mutual orientations of molecules) or major (leading, for instance, to substantially different atomic arrangements). Sometimes other terms are used for the phenomenon. Thus, when concerning different forms of the elements, the word allotrope is used, instead of polymorph. Also, polymorphs which have structures differing in the stacking sequence of layers (for example, in silicon carbide) are called polytypes.

A somewhat similar phenomenon is the ability of many compounds to incorporate solvent molecules in their structure during crystallization from solution. Thus compounds frequently exist in both anhydrous and hydrated forms, the crystal structures of which may be essentially identical or profoundly different. Other solvent molecules, such as acetone and chloroform, may be similarly incorporated. Ultimately this relates to the existence of clathrates, for which the structure may only be stable when both host and guest molecules are present. Sometimes hydrates lose water readily; on other occasions anhydrous forms may be hygroscopic. Although this article will concentrate on true polymorphism, the 'pseudopolymorphism' of solvates, which can carry similar NMR connotations, will be mentioned at times.

Of course, another closely-related topic is that of phase changes and phase diagrams, together with similar matters concerning the formation and interchange of polymorphic forms. These questions will be largely ignored in the present article. Under given conditions of temperature, pressure, etc., only one polymorph will clearly be favored by thermodynamic considerations. Frequently, however, kinetics of interconversions will be slow, and several forms will exist at ambient temperature and pressure for times in excess of the minimum required to obtain NMR spectra. Such metastable forms may be obtained, for instance, by crystallization from a solvent or by quenching from a temperature at which they are stable. The present article will concentrate on NMR data obtained under standard

working conditions (atmospheric pressure and ambient temperature).

Cases of polymorphism and related phenomena may be divided into those involving molecular crystals and those relating to macromolecular structures (in one, two, or three dimensions). Of course, the bonding in the latter implies that interconversion between forms (e.g. between graphite and diamond) is extremely difficult. Indeed, it might be argued that cases of macromolecular structural differences, which require bond-breaking for interconversion (as for silicon carbide) are not properly labeled as polymorphic since they are more analogous to some types of isomerism in organic compounds. However, although interconversions between molecular polymorphs are usually relatively easy, it must not be assumed that intermolecular forces are negligible. Frequently they involve hydrogen bonding, with substantial energies.

Polymorphism is particularly important, and has been extensively investigated by NMR, for pharmaceutical compounds, for silicates and zeolites, for polymers (including naturally occurring materials such as cellulose and chitosan, as well as synthetic polymers), and for ceramic materials.

2 APPLICABILITY OF NMR

Since the electronic environments of corresponding atoms in different polymorphs of the same compound differ, the NMR chemical shifts will be in principle distinguishable. Indeed, the total NMR spectrum can clearly act as a fingerprint to identify polymorphic forms. Such differences are expected to be similar in magnitude to the crystallographic splittings observed when molecules or atomic groupings of the same chemical type are in locations in the unit cell unrelated by symmetry. The 'fingerprint' is of the crystallographic asymmetric unit, and simply counting the number of resonances may, on occasion, suffice to distinguish between polymorphs.

The techniques most commonly used to distinguish polymorphs are DSC, IR, and powder XRD, but all three have disadvantages. The DSC method is very crude, since it gives little or no chemical information. IR spectroscopy often suffers from lack of resolution and from difficulties in interpreting intensities. Powder XRD is often the preferred technique, but it is not sensitive to poorly crystalline or amorphous forms. NMR does not suffer from any of these problems, and the only drawback is the cost of the equipment.

Polymorphs often differ in molecular-level mobility, and hence in NMR relaxation times, but these are unlikely to be used as distinguishing features, except perhaps for polymeric systems.

3 MOLECULAR POLYMORPHS

The principal area of investigation of molecular polymorphism is that of pharmaceutical compounds. This is for very practical reasons: polymorphs sometimes show differing physiological activity (largely as a result of differences in rates of dissolution) and government regulations therefore require pharmaceutical companies to identify carefully the polymorphic form of their products. Moreover, very small changes in

conditions of preparation can readily result in a difference in polymorphic form, and scale-up can reveal problems not found in laboratory synthesis, so that an understanding of polymorphic variations is very important in pharmaceutical chemistry.

The first application of ^{13}C CP MAS NMR to pharmaceutical polymorphism appears to be that reported by Balimann et al.¹ in 1981, which featured spectra of two forms of Nolvadex (the ICI trade name for the generic tamoxifen). In the late 1980s and early 1990s the groups of Byrn^{2,3} and of Harris⁴⁻⁶ were particularly active in this area.

Steroids appear to be particularly prone to give rise to polymorphic forms. Cortisone acetate (**1**) is a typical example. A substantial number of polymorphs and solvated forms are known, and seven have been studied⁴ by MAS NMR. Three of the polymorphs are anhydrous, and Figure 1 illustrates the ^{13}C CP MAS spectra for the high-frequency region (containing resonances from C-3, C-5, C-11, C-20 and C-22).

Immediately, two important conclusions can be made:

1. NMR readily distinguishes the three anhydrous forms (as it does the five hydrates and other solvates).
2. Whereas Forms I and II have asymmetric units consisting of a single molecule (since only five signals are seen in this region), Form III is more complex. In fact, expanded-scale spectra for all the carbon resonances show that Form III has three molecules in the asymmetric unit.

One can go further when peak assignments are firmly established. The apparent variation in the relative intensities of the two peaks on the right in Figure 1(a) and (b) arises from differing spinning sideband intensities. Complete analysis of the spinning sideband manifolds (at low spin rates) shows that C-5 and C-22 have distinguishable shielding anisotropies and asymmetries, which in turn indicates that the order of their isotropic chemical shifts is interchanged between Forms I and II. This variation can be correlated with hydrogen

Figure 1 Carbon-13 CP MAS NMR spectra⁴ (high-frequency region only) of three polymorphs of cortisone acetate (**1**) at 50.3 MHz

Table 1 Isotropic Chemical Shifts^a for C-3, C-5, and C-22 of the Anhydrous Polymorphs of Cortisone Acetate

Carbon	Form I	Form II	Form III
C-3	202.8 ^b	198.9	203.0 ^c , 203.0 ^c , 198.2
C-5	175.7	171.0	173.7, 173.7, 166.9
C-22	169.8	175.2 ^b	174.3 ^c , 171.5, 170.3

^aGiven as δ_{C} (ppm).

^bShown by X-ray crystallography to be the acceptor site for hydrogen bonding.

^cConcluded from the NMR evidence to be the acceptor site for hydrogen bonding.

bonding,^{2,4} which causes an increase in chemical shift of 3–4 ppm at the acceptor carbonyl carbon resonance. Table 1 shows the assignments for carbons C-3, C-5 and C-22 for the three anhydrous forms, and indicates the known acceptor positions for hydrogen bonding. One can conclude that, of the three molecules in the asymmetric unit of Form III, two are hydrogen bonded at C-3 and the third, in contrast, at C-22. It may be noted that conjugation appears to relay the effect of hydrogen bonding on the chemical shift from C-3 to C-5.

This example illustrates how polymorphic form can affect chemical shifts. Unfortunately, matters are not often so simple. The differences in chemical shifts between analogous carbons for different polymorphs may arise either from *intermolecular* effects (packing, direct influence of neighboring molecules, hydrogen bonding, etc.) or *intramolecular* effects (variations in geometry and/or conformation). There is rarely any way that NMR can distinguish between the two influences. Of course, if crystal structures are known from X-ray studies, then knowledge of influences on chemical shifts obtained from solution state studies or by theory can be brought to bear. A case where intramolecular differences (but correlated with intermolecular differences!) are thought to be important is that of 4'-methyl-2'-nitroacetanilide (**2**), which exists in two forms (white and yellow), both of which have been subjected to study by single-crystal X-ray diffraction. In the white form, both the amide and nitro groups are in planes at a substantial angle (ca. 44°) to the plane of the aromatic ring, giving restricted conjugation and preventing intramolecular hydrogen bonding. On the other hand, the yellow form (with two molecules in the asymmetric unit) has more nearly coplanar groups (dihedral angles between 12° and 31°), allowing intramolecular hydrogen bonding between the amide NH and one of the nitro group oxygens. These facts suffice to explain the differences in chemical shifts between the polymorphs.⁵ For example, the white form (C–NO₂ dihedral angle, 44.0°) has $\delta(\text{C-2}) = 144.1$ ppm whereas the yellow form (C–NO₂ dihedral angles, 18.0° and 12.3°) gives $\delta(\text{C-2}) = 135.9$ and 133.0 ppm (presumably respectively).

Certain simple but important measurements can be made of polymorphism via the fingerprinting ability. For example:

1. Mixtures of polymorphs can be readily studied and minor components can be quantified,⁴ in favorable cases down to the 1% level.
2. NMR spectra can be used to monitor the polymorphic variations produced by different formation conditions (e.g. different rates of crystallization produced by cooling a solution quickly or slowly).⁴
3. Polymorphism can be studied directly in pharmaceutical tablets. Saindon et al.³ have pointed out that the CP MAS technique can be used to discriminate against signals deriving from the excipient.

The combination of single-crystal XRD and CP MAS NMR for the study of polymorphism is particularly powerful. The former can give precise atomic positions but is frequently feasible for only some of the forms of a product (because of difficulties in growing suitable crystals). NMR, however, can almost always be relied upon to yield spectra of all polymorphs available in sufficient quantity, and interpretation is greatly aided by X-ray information on any one form. For example, of the two forms of fosinopril sodium, one was examined using single-crystal X-ray diffraction techniques, then both were studied⁷ by CP MAS NMR of ¹³C. The results provided by NMR enabled the conclusion to be drawn that the environment of the acetal side chain of fosinopril sodium differed in the two polymorphs. In this case ³¹P CP MAS NMR was also used, and showed a significant chemical shift difference (2.2 ppm) between the forms.

It is possible to detect conformational disorder within polymorphs by CP MAS NMR. Thus Stoltz et al.⁸ have shown that peak intensities for the monohydrate of oxyphenbutazone give a site ratio consistent with X-ray results in terms of sterically-favored isomers. However, it must be said that since CP MAS NMR spectra are obtained on microcrystalline or powdered material, it is not easy to differentiate between mixed crystals and disorder in a single type of crystal.

Differences in bonding between polymorphs can sometimes be quite startling but readily detectable by NMR. Thus, for 2-aminobenzoic acid (**3**), ¹³C MAS NMR reveals⁹ that Form I gives two signals each for C-1 and C-2. These are at chemical shifts which are characteristic of the normal and zwitterionic structures (**3**)A and (**3**)B, respectively, indicating that the unit cell contains equal proportions of each form. On the other hand, Forms II and III give spectra showing that each has an asymmetric unit containing one molecule of structure (**3**)A only.

Interestingly, the ¹³C spectra of Forms II and III are so similar as to be virtually indistinguishable. In these cases, it is necessary to turn to nuclei other than ¹³C to differentiate. The proton CRAMP spectra of the two forms are, in fact, very different (Figure 2). Form II of the compound gives a

Figure 2 Proton CRAMP spectra⁹ of two polymorphs of 2-aminobenzoic acid (**3**) at 200.13 MHz. The sample of Form III contains a small amount of Form II, which gives rise to the hydrogen-bonded peak at δ 12.3 ppm. The peak at $\delta \sim 1.5$ ppm in each spectrum is due to an impurity in the Kel-F rotors used. The broad line (assigned to NH_2 and CO_2H protons) underlying the spectrum of Form III is clearly visible

strong signal at $\delta_{\text{H}} = 12.3$ ppm, indicative of a hydrogen-bonded CO_2H group (in agreement with single-crystal X-ray results). This is not present for Form III (the crystal structure of which is unknown)—from which it can be deduced that hydrogen bonding is probably absent. However, the situation is complicated by the fact that there are proton-exchange processes occurring, involving amino and (in some cases) carboxylic acid protons, at a rate comparable with the NMR timescale, producing broad bands underlying the sharper aromatic proton signals at ambient probe temperature.

4 POLYMORPHISM AND MOLECULAR MOBILITY

In addition to the effects on chemical shifts arising from differences in intermolecular environment and intramolecular geometry between molecules of different polymorphs, variations in molecular level motion can often also be detected. A case in point is illustrated in Figure 3, which shows ambient probe temperature ¹³C CP MAS spectra¹⁰ of two forms

Figure 3 Carbon-13 CP MAS spectra¹⁰ of two forms of bisphenol-A diacetate (**4**) at 50.3 MHz and ambient probe temperature. Signals not indicated by numbers in (a) [and corresponding peaks in (b)] are spinning sidebands

of bisphenol-A diacetate (**4**). Clearly, Form I gives a much more complex spectrum than Form II, as is consistent with the single-crystal X-ray results, which show that in the former case the asymmetric unit consists of two entire molecules. The second feature of importance is the breadth of the resonances for the aromatic CH carbons (C-4, C-5, C-7 and C-8) for Form II, which suggests there is substantial averaging, probably arising from 180° ring-flips of the phenylene rings (possibly by simultaneous motion of the two halves of the molecule). This suggestion is readily confirmed by variation of the temperature.

Such variable temperature ¹³C CP MAS NMR experiments have been used¹¹ to study the motion of a phenylene ring about the *para* axis of one form of sulfanilamide, (**5**). Just below room temperature the C-3/C-5 resonance (but not the C-2/C-6 signal) is observably split because the SO₂NH₂ substituent

is twisted with respect to the ring. An Arrhenius activation energy, E_a , of $63 \pm 4 \text{ kJ mol}^{-1}$ for the (assumed) 180° ring-flip was obtained. It should be noted that rapid motion of this type would not be detected by XRD.

An example from an entirely different area of chemistry concerns the polymorphism of phosphorus pentachloride, PCl₅. The stable form (Phase II) of this compound under normal conditions is ionic, with the structure PCl₄⁺ PCl₆⁻. Both ions are very mobile at ambient temperature, so that shielding anisotropy at the phosphorus nuclei is eliminated and the chlorine nuclei relax very rapidly. The latter effect causes self-decoupling of the chlorines and the net effect is that ³¹P MAS spectra consist¹² of two sharp lines, one for each anion. However, Phase III, which can also be studied at ambient probe temperature, has the stoichiometry [PCl₄]₂⁺[PCl₆]₂⁻Cl⁻. Since this form, like Phase II, contains PCl₄⁺ and PCl₆⁻ ions, the ³¹P MAS spectrum also consists of two bands, but at 81 MHz the resonances are broad and splittings arising from (Cl,P) coupling are seen at 36 MHz. Thus self-decoupling is substantially less efficient for Phase III than for Phase II, probably indicating more restricted rotational mobility for the ions in the former.

5 MACROMOLECULAR POLYMORPHS

Two types of example from widely different chemical areas should suffice to show some of the general features of polymorphism in macromolecular systems. Silicon carbide exemplifies the situation where the structure is three-dimensional so that interchange between forms is not feasible. The different polymorphs are essentially frozen-in at the time of preparation. All structures have alternating Si and C atoms, with all coordinations tetrahedral (though mostly not with the full symmetry). The structural differences between some of the forms can be appreciated from Figure 4, which shows a plane including the *c* crystallographic axis and alternating Si and C atoms in that plane for four forms of the material. It is evident that the detailed environments of all silicon atoms of the 2H form are equivalent, as is also the case for the β form (though β and 2H environments are not identical). However, the 4H form contains two types of Si and the 6H three types. The ²⁹Si spectra (Figure 5) show¹³ the expected number of signals for the four forms. Similar considerations apply to the ¹³C spectra. There is also a range of other forms. Assignment of the signals for the 4H and 6H polymorphs is not easy but has been made.^{13,14} The separate signals have different relaxation times, probably as a result of the presence of impurities. Silicon carbide is a case where the amorphous material can also exist, without sizable domains of any of the potentially ordered structures. Such material gives rise to broad ²⁹Si and ¹³C resonances, usually characterized by shorter values of *T*₁ than the crystalline material, probably because impurities tend to concentrate in amorphous regions.

Of course, silica provides the outstanding example of a compound with multiple polymorphs. Not only are there well-characterized crystalline forms (quartz, cristobalite, tridymite, etc.), together with the common amorphous glass, but it seems that many types of zeolites can be obtained with all aluminum atoms replaced by silicon so that they become silica polymorphs. Since zeolites are treated in other entries in this Encyclopedia they will not be discussed here. The book

Figure 4 Schematic structures for silicon carbide polymorphs. The vertical arrows represent repeat distances

Figure 5 Silicon-29 MAS NMR spectra¹³ of silicon carbide polymorphs at 59.58 MHz: (a) 3C (β); (b) 2H; (c) 4H; and (d) 6H

by Engelhardt and Michel¹⁵ contains a useful discussion of NMR studies of nonzeolitic silica polymorphs (pp. 170–175). The ^{29}Si chemical shifts cover a wide range ($\delta_{\text{Si}} \sim -107$ to -121 ppm), the variation being attributed to differences in mean SiOSi bond angles, α , an increase in shielding resulting from widening SiOSi angles. A number of specific relationships have been proposed,¹⁶ including (from theoretical considerations) $\delta_{\text{Si}} = -247.05\rho + 2.19$, where $\rho = \cos \alpha / (\cos \alpha - 1)$. Of course, many of the silica polymorphs differ in the number of different crystallographic sites. Coesite, for instance, gives two widely-spaced ^{29}Si signals ($\delta_{\text{Si}} = 108.1$ and

113.9 ppm), in accord with its structure.¹⁶ In contrast to all the four-coordinate silica polymorphs, stishovite, which contains six-coordinate silicon, gives a signal at $\delta_{\text{Si}} = -191$ ppm.¹⁶ As with silicon carbide, amorphous forms of silica (glass!) are well known.

Organic polymers may also show polymorphism. One of the early examples of CP MAS NMR related to the case of isotactic polypropene, which exists in several crystalline forms usually as domains separated by amorphous material. In effect, the chains constitute infinite one-dimensional bonded structures with weaker forces between the chains. The systems therefore are intermediate between the molecular polymorphs discussed in Section 3 and the infinite three-dimensional structures of SiC and SiO₂. The structure of the α form of polypropene is shown in Figure 6(a). The helical polymer units occur as pairs of interlocking chains with opposing handedness. This creates a situation where there are two distinct methyl sites, with two-thirds of the groups in a given helix facing the companion helix, and the remaining third facing outwards. Thus a 2:1 doublet is expected for the methyl carbons, and this is observed¹⁷ in practice. A similar situation obtains for the CH carbons.

In contrast, the crystal structure of the β form contains separate groups of helices of the two types of handedness, with no pairing [Figure 6(b)]. The NMR spectrum therefore lacks the well-defined splitting shown by that of the α form.

Figure 6 Diagrammatic crystal structures for two forms of isotactic polypropene: (a) α form; (b) β form. The figures show projections of the chains perpendicular to their axes, with the corners of the triangles indicating the positions of methyl groups. The arrows represent the handedness of the helices

Of course, isotactic polypropene also contains a significant proportion of amorphous material which, as usual, gives rise to somewhat broadened CP MAS ^{13}C lines. The differences between the α and β forms of isotactic polypropene arise from intermolecular packing of the polymer chains. Far greater differences occur, as expected, in NMR spectra^{17,18} for polymer forms differing in tacticity (such as isotactic and syndiotactic polypropene). However, differences in tacticity are not normally classed under polymorphism.

Biochemical polymers such as cellulose and chitosan also give rise to polymorphism, which has been studied by solid state NMR methods.^{19,20}

1 REFOCUSING AND DEPHASING

Rotational echo double resonance (REDOR) NMR is a new analytical spectroscopic technique for solids spinning at the magic angle which has been developed during the last 6 years.¹ REDOR provides a direct measure of heteronuclear dipolar coupling between isolated pairs of labeled nuclei. In a solid with a ^{13}C – ^{15}N labeled pair, for example, the ^{13}C rotational echoes that form each rotor period following a ^1H – ^{13}C cross polarization transfer can be prevented from reaching full intensity by insertion of a ^{15}N π pulse each half rotor period (Figure 1). The ^{15}N pulse in the middle of the evolution period is replaced by a ^{13}C pulse so that isotropic carbon chemical shifts are in phase at the beginning of data acquisition. The REDOR difference (the difference between a ^{13}C NMR spectrum obtained under these conditions and one obtained with no ^{15}N π pulses) has a strong dependence on the ^{13}C – ^{15}N dipolar coupling and hence the ^{13}C – ^{15}N internuclear distance.² REDOR is described as double resonance even though three radiofrequencies (typically ^1H , ^{13}C , and ^{15}N) are used because the protons are removed from the important evolution part of the experiment by resonant decoupling. The dephasing of magnetization in REDOR arises from a local dipolar ^{13}C – ^{15}N field gradient and involves no polarization transfer. REDOR has no dependence on ^{13}C or ^{15}N chemical shift tensors and does not require resolution of a ^{13}C – ^{15}N coupling in the chemical shift dimension.²

The evolution of observable S -spin magnetization for a single crystallite on resonance under magic angle spinning and an I – S dipolar coupling is shown in Figure 2 (left). Each dot represents the result of evolution for an equal fraction of a rotor period, with a minor homogeneous decay superimposed for display purposes. At the beginning of the rotor cycle, the magnetization is the observable, $\langle \hat{S}_x \rangle$. Under sample rotation and I – S dipolar coupling, the observable magnetization is transformed into nonobservable bilinear coherence, $\langle \hat{I}_z \hat{S}_y \rangle$, and then back into $\langle \hat{S}_x \rangle$. By the end of the rotor cycle the full observable magnetization has been recovered. For a collection of crystallites in a powder, individual phase accumulations (the product of resonance frequency and time) vary in size and sign depending on crystallite orientation in the magnetic

Figure 1 Pulse sequence for a version of REDOR ^{13}C NMR. Two equally spaced, ^{15}N 180° pulses per rotor period result in the dephasing of transverse carbon magnetization produced by a cross-polarization (CP) transfer from dipolar-coupled protons. Carbon–nitrogen dipolar coupling determines the extent of dephasing. A ^{13}C 180° pulse replaces the ^{15}N pulse in the middle of the dephasing period and refocuses isotropic ^{13}C chemical shift differences at the beginning of data acquisition. After the CP transfer, resonant decoupling removes the protons from the experiment. The illustration is for four rotor cycles

field. This causes phase interference during the rotor cycle and an apparent decay of the observable signal for the powder. Nevertheless, because the magnetization from each crystallite refocuses completely, the dephasing for the powder is also refocused into a full rotational echo at the end of the rotor cycle.

However, even for a single crystallite, the refocusing is incomplete in the presence of dephasing I -spin π pulses (Figure 2, right). Evolution for the crystallite is identical to that shown at the left of the figure between times ‘1’ and ‘2’. The I -spin inverting π pulse, which ends at time ‘3’, changes the sign of $\langle \hat{I}_z \hat{S}_y \rangle$. This process is repeated under the second I -spin π pulse which ends at time ‘5’. At the end of the rotor cycle (time ‘6’), the transformation of bilinear coherence created during the rotor cycle into observable magnetization is incomplete. For a powder, a rotational echo of diminished intensity is observed. The extent of the diminution depends on the I – S coupling. The diminution is maximum for two dephasing pulses and is independent of their exact placement so long as the pulse spacing is one-half of the rotor period.²

2 REDOR DEPHASING FOR RECRYSTALLIZED LABELED ALANINES

The results of a REDOR experiment performed using the pulse sequence of Figure 1 on an equimolar, recrystallized mixture of L-[2- ^{13}C , ^{15}N]alanine and L-[1- ^{13}C]alanine are shown in Figure 3.³ The full echo ^{13}C NMR spectrum (S_0) after two rotor cycles with no dephasing is at the bottom of the Figure, and the REDOR difference ($\Delta S = S_0 - S$, where S is the spectrum with dephasing) as a function of the number of rotor cycles, is shown at the top of the Figure. The 900 Hz intramolecular ^{13}C – ^{15}N coupling results in a sizeable ΔS for the methine carbon atom after only two rotor cycles; this ΔS reaches a maximum after four rotor cycles, and then oscillates in amplitude. The average 100 Hz intermolecular coupling produces a small carboxyl carbon atom ΔS after two rotor cycles, which increases monotonically with dephasing time.

Figure 2 Schematic diagram of the evolution of the IS density matrix for a single crystal under magic angle spinning and $I-S$ dipolar coupling during a REDOR pulse sequence with no dephasing pulses (left) and with dephasing pulses (right)

Figure 3 The 50.3-MHz REDOR ^{13}C NMR spectra of an equimolar, recrystallized mixture of L-[2- ^{13}C , ^{15}N]alanine and L-[1- ^{13}C]alanine, as a function of the number of rotor cycles. A full echo spectrum (S_0) after two rotor cycles is shown at the bottom of the Figure and REDOR difference spectra (ΔS) at the top. Magic angle spinning was at 2702 Hz

The $\Delta S/S_0$ ratios for both carbon atoms have the same dependence on the dimensionless parameter, λ_D (Figure 4, solid circles and squares). The theoretical dependence (Figure 4, solid line) was calculated by performing an isotropic powder average over the dephasing for individual crystallites (Figure 2, right). Thus, the angular dependence of the dipolar interaction is suppressed. The resulting universal dephasing behavior needs to be calculated only once for all heteronuclear spin-1/2 pairs. (REDOR applications also include quadrupolar nuclei like ^2H , with either direct observation of deuterium or indirect observation through REDOR dephasing. Calculation of the theoretical $\Delta S/S_0$ behavior is slightly more complicated.)⁴

Figure 4 Observed dependence of $\Delta S/S_0$ on the universal parameter, λ_D , for the ^{13}C - ^{15}N double-labeled alanine mixture of Figure 3. (N is the number of rotor cycles with dephasing, D is the dipolar coupling constant, and T_r is the rotor period)

A few experimental values of $\Delta S/S_0$ determine λ_D , which then establishes D since the total dephasing time (the product of the number of rotor cycles of dephasing and the rotor period) is known. Because $D = \gamma_I \gamma_S \hbar / 2\pi r^3$, the observed dephasing can be translated into an internuclear distance directly. If $\Delta S/S_0$ and hence D are known experimentally to 10%, the distance is known with 2% accuracy. Weak dipolar couplings associated with large internuclear distances can be effectively amplified in REDOR by simply allowing the rotor to go around. The only practical problem is holding the echo train together. This depends on the technical difficulty of completely decoupling the protons, which may require low temperatures to suppress kHz regime molecular motions.⁵ Translating dipolar couplings into distances in the presence of large-amplitude motions involves specifying a model for the motion.⁶

3 LONG-RANGE COUPLINGS AND THE NATURAL-ABUNDANCE BACKGROUND

In the early applications of REDOR to C–N distance determinations in peptides, relatively few dephasing pulses were used so that sometimes large natural-abundance corrections were necessary.⁷ More recently, increased dephasing has been possible as a result of the development of phase routing schemes⁸ (Figure 5) that eliminate the dependence of REDOR determinations on frequency offsets and pulse imperfections.⁹

For example, the ^{13}C signal for the label in the nine-residue emerimicin fragment, Ac-Phe-[1- ^{13}C]MeA₂-MeA-MeA-Val-[^{15}N]Gly₆-Leu-MeA-MeA-O-Bzl, where Ac = acetyl, Phe = phenylalanine, MeA = methylalanine, Val = valine, Gly = glycine, Leu = leucine, Bzl = benzyl is not resolved from that of natural-abundance peptide carbonyl carbon atoms, which make a constant 7.7% contribution to the full echo signal, S_0 . This correction can either be measured in a separate experiment on a natural-abundance sample, or calculated from the known structure.¹⁰ In addition, the natural-abundance ^{13}C carbonyls of Val₅ and Gly₆ are, respectively, one and two bonds away from the ^{15}N label and so will make a contribution to ΔS that reaches a maximum value of 2% by about $N_c = 16$. The other natural-abundance carbonyl ^{13}C atoms are all farther away from the ^{15}N label than is the

Figure 5 REDOR pulse sequence with dephasing π pulses on both the nitrogen and carbon channels. The pulses are applied using an xy -8 phase cycling scheme to eliminate offset effects and pulse imperfections. Signal acquisition begins two rotor cycles after the completion of a full $8N$ rotor cycles of dephasing. CP = cross polarization. Acq = acquisition

Figure 6 Observed dependence of $\Delta S/S_0$ on the universal parameter, λ_D , for a ^{13}C – ^{15}N double-labeled fragment of emerimicin. The pulse sequence of Figure 5 was used. The experimental results (solid circles) are in agreement with calculation (solid line) assuming a ^{13}C – ^{15}N dipolar coupling of 40 Hz corresponding to a C–N distance of $4.1 \pm 0.1 \text{ \AA}$. The natural-abundance correction to $\Delta S/S_0$ at $N_c = 8$ is 50% and at $N_c = 100$ is 4%

carbonyl label at MeA₂. Thus, for $N_c > 32$, the observed ΔS is dominated by the coupling of the ^{15}N – ^{13}C labels and additional natural-abundance corrections are unimportant. By $N_c = 96$, $\Delta S/S_0$ is greater than 0.7 (Figure 6), consistent with a D value of 40 Hz, corresponding to a C–N distance of $4.2 \pm 0.1 \text{ \AA}$. The distance by X-ray analysis¹¹ is $4.16 \text{ \AA}$. The natural-abundance correction to D is less than 2 Hz when $N_c = 96$, which means that less than a 0.05- $\text{\AA}$ correction for the C–N distance is required. The agreement between X-ray and REDOR determinations of the [1- ^{13}C]MeA₂–[^{15}N]Gly₆ distance for this calibration sample for $N_c = 8$ to $N_c = 112$

Figure 7 Pulse sequence for TEDOR I – S NMR. Following a cross-polarization (CP) transfer from abundant protons to generate initial I -spin magnetization, the effect of the protons is removed by resonant decoupling. The π pulses are shown separated by one-half rotor periods. The coherence transfer is achieved by simultaneous $\pi/2$ pulses in the middle of the evolution period. The solid circles represent observable magnetization

Figure 8 Schematic diagram of the evolution of the density matrix for a powder during the TEDOR pulse sequence of Figure 7 before the coherence transfer pulses (left) and after the application of the transfer pulses (right). The phase angle between $\langle \hat{I}_x \rangle$ and $\langle \hat{I}_y \hat{S}_z \rangle$ for each rotor cycle is indicated by the solid circles and is calculated using the technique illustrated in Figure 2 (right) together with a powder average. The effect of the 90° pulses is to permute I and S subscript indices

confirms that with the compensation of the $xy-8$ phase cycling scheme, hundreds of dephasing pulses can be used with no significant accumulation of error for a REDOR difference.¹⁰ A few, accurate long range distance determinations are often sufficient to establish unambiguously the local conformation of a peptide or protein.¹²

Figure 9 Transferred-echo double-resonance (top) and cross-polarization, magic angle spinning (CP MAS, bottom) ^{13}C NMR spectra of a recrystallized equimolar mixture of L-[2- ^{13}C , ^{15}N]alanine and L-[1- ^{13}C]alanine. The TEDOR spectrum was obtained using three rotor cycles each of dephasing and refocusing. This is insufficient to generate significant carboxyl-carbon magnetization because the average intermolecular C–N dipolar coupling is weak

Figure 10 Pulse sequence for TEDOR combined with REDOR. The TEDOR part of the experiment (which for this illustration extends over the first four rotor cycles following the H–N cross polarization transfer) selects ^{13}C magnetization by a coherence transfer from ^{15}N . The REDOR part of the experiment (broken brackets) immediately follows the TEDOR preparation and measures dipolar coupling of the selected ^{13}C to ^{19}F . REDOR dephasing is performed using the phase-routing scheme illustrated in Figure 5. Two rotor cycles are added to the sequence so that the start of data acquisition is not coincident with a pulse

Figure 11 TEDOR–REDOR ^{13}C NMR spectra of a ^{19}F , ^{13}C , ^{15}N -labeled emerimicin (see Figure 6). The TEDOR spectrum (bottom) was obtained using an N–C coherence transfer as illustrated in Figure 7. The TEDOR–REDOR difference spectrum (the difference between TEDOR spectra with and without dephasing REDOR pulses) is shown at the top of the Figure. This spectrum was obtained by ^{19}F dephasing of the ^{15}N -TEDOR-selected ^{13}C magnetization over 40 rotor cycles

Background corrections for ^{13}C -observe ^{15}N -dephase REDOR are relatively simple to calculate because the ^{15}N natural abundance is low and γ_{N} is small. A measured value involves a separate sample with no ^{15}N label. The minor, observed $\Delta S/S_0$ for the single-labeled sample is then usually just subtracted from that for the double-labeled sample.³ The correction is more involved for ^{13}C - ^{31}P and ^{13}C - ^{19}F pairs. For example, a ^{19}F -observe ^{13}C -dephase REDOR experiment designed to measure the dipolar coupling for a labeled ^{19}F - ^{13}C pair separated by 10 Å must take into account the sizeable number of natural-abundance ^{13}C atoms within dephasing range of the ^{19}F . One way¹³ to interpret the observed $\Delta S/S_0$ is to generate a model lattice with 1% randomly distributed ^{13}C . If all ^{13}C - ^{13}C coupling is ignored, the ^{19}F -observed, ^{13}C -dephase REDOR ΔS can be interpreted in terms of a collection of independent, $^{19}\text{F}(\text{label})$ - $^{13}\text{C}(\text{label})$ - $^{13}\text{C}(\text{natural abundance})$, three-spin clusters, whose dipolar-tensor orientations are known from the lattice parameters.

4 COHERENCE TRANSFER AND SELECTIVITY

Sometimes a natural-abundance background cannot be measured or calculated easily. In this situation, the dipolar-coupled spins can be selected from among the background of uncoupled spins by a coherence transfer from one spin of

the heteronuclear pair to the other. The pulse sequence for this selection is shown in Figure 7. Transverse magnetization is first established in the I -spin system by a cross-polarization transfer from abundant protons. The dephasing of I -spin magnetization by dipolar-coupled S spins through rotor-synchronized S -spin π pulses leads to a bilinear coherence (Figure 8, left) that is transferred by an I, S pair of $\pi/2$ pulses (Figure 8, shaded arrow). These pulses occur together at the completion of a rotor cycle (Figure 7) and interchange the indices of the bilinear coherence. Finally, the transferred bilinear coherence is transformed into observable S -spin transverse magnetization by rotor-synchronized I -spin π pulses (Figure 8, right). The entire procedure is called transferred echo double resonance (TEDOR).¹⁴ TEDOR is a rotor-synchronized solid state experiment which is based on some of the same coherence transfer principles as the INEPT solution state experiment.

The results of a TEDOR experiment using the pulse sequence of Figure 7 performed on the mixed double-labeled alanine sample discussed above are shown in Figure 9. Proton polarization is first transferred to nitrogen atoms. Then three rotor cycles are used to create bilinear ^{15}N - ^{13}C coherence, and three more rotor cycles to produce observable methine carbon atom magnetization following the coherence transfer. The TEDOR theoretical transfer efficiency¹⁴ is 50% compared with the observed 35% (Figure 9). Because TEDOR is not a difference experiment, TEDOR has the same theoretical sensitivity as REDOR. No sizeable carboxyl

Figure 12 Two schemes for REDOR. (Left) Acquisition of a time domain signal follows evolution during which dephasing pulses diminish observable magnetization and create nonobservable I - S bilinear coherence. This scheme is suitable for multiline spectra and a separate $\Delta S/S_0$ is measured for each line in the spectrum. The dependence on λ_D is determined by varying the number of rotor cycles. (Right) Synchronous detection of a time domain signal during evolution is suitable for a single-line spectrum. The observed S/S_0 is $1 - (\Delta S/S_0)$. AQ = acquisition; SAQ = synchronous acquisition

carbon magnetization is observed in Figure 9 because the short evolution time was insufficient for the weak intermolecular ^{15}N – ^{13}C coupling to create significant bilinear coherence. If there had been a collection of nitrogen atoms all with comparable strong, couplings to carbon atoms, the TEDOR coherence transfer could still have been made selective by alternating the sign of the starting nitrogen magnetization for just one type of ^{15}N by DANTE inversion of the selected nitrogen atom signal every other scan.¹⁵ The sign of the transferred bilinear coherence would then alternate, as would that of the observed carbon atom magnetization corresponding to the selected ^{15}N – ^{13}C coupling. Data routing could then discriminate between carbon signals.

5 COMBINATION EXPERIMENTS AND SYNCHRONOUS DETECTION

TEDOR can be used alone or in combination to make highly selective TEDOR–TEDOR and TEDOR–REDOR experiments.¹⁶ The pulse sequence for the latter is illustrated in Figure 10. A TEDOR sequence is tailored to select the carbonyl carbon atom signal of residue 4 of a ^{19}F , ^{13}C , ^{15}N triple-labeled emerimicin fragment (Figure 11). The ^{15}N – ^{13}C selected magnetization is then dephased by REDOR ^{19}F π pulses resulting in the determination of a selected 8-Å C–F distance. This combination experiment involves four radiofrequencies in the same sequence which is possible using transmission-line probe technology.¹⁷ The tuning elements in these probes are outside the magnet in a large, shielded box with isolation of all radiofrequencies, making high power on four channels practical.¹⁸

The observed signal in the TEDOR–REDOR experiment can be detected either as part of a two-dimensional experiment in which full S and S_0 spectra are obtained by normal

Figure 13 Simulation of X-spin REDOR dephasing of I – S TEDOR-selected S -spin magnetization (solid line). The simulation assumed an I – S coherence transfer after two rotor cycles of dephasing, followed by two rotor cycles of transformation of coherence into observable S -spin magnetization (see Figure 7). For $S/S_0 > 0.5$, the simulation is almost independent of orientation of I – S and S – X dipolar tensors (results not shown) and closely matches that for a full isotropic powder (dotted line). All simulations were performed assuming that the I – S coupling was 1.2 kHz, the S – X coupling was 100 Hz, and the magic angle spinning was 5 kHz

acquisition starting with a rotor cycle (Figure 12, left), or synchronously with one sampling per rotor cycle (Figure 12, right). The former is used for complicated spectra with more than one resonance even after selection by TEDOR. The latter is used for the simple, one-line spectra that usually result from a TEDOR preparation. Synchronous detection² has the sensitivity advantage of generating the entire REDOR dephasing pattern in real time. The dipolar evolution dimension can be mapped by variation of the number of rotor cycles,¹ or variation of the position of the dephasing pulse within the rotor period.² The latter has a constant total dipolar evolution time which eliminates the echo-train lifetime from the analysis. In both of these two-dimensional methods, spins which contribute to the S -spin signal but have no I – S coupling (a common situation for a natural-abundance background) do not interfere with the determination of the I – S interaction.¹⁶ Such spins produce a constant offset in the dipolar time domain and so a zero-frequency spike in the dipolar frequency domain. The I – S coupling is determined by the width of the dipolar spectrum.²

Even an efficient TEDOR transfer does not result in observable magnetization associated with an isotropic powder. Thus, some crystallite orientations are discriminated against depending on the orientation of the IS and SX dipolar tensors in an I – S – X three-spin TEDOR–REDOR experiment. Nevertheless, following an efficient I – S TEDOR transfer, the *initial* S -observe, X -dephase REDOR behavior depends only on the size of the dipolar tensors and not on their orientation (Figure 13). Thus, interpretation of the 20% dephasing (Figure 14) in a TEDOR–REDOR experiment on the triple-labeled peptide of Figure 11 does not require knowledge of ^{15}N – ^{13}C – ^{19}F geometry in order to extract a C–F distance.¹⁶ This will be the situation for most long-range distance determinations in general, simply because little dephasing is observed and determination of the dipolar coupling is based on the initial S/S_0 behavior. However, for systems with stronger couplings, Fourier transforms of the TEDOR–REDOR dipolar evolution offer the opportunity to establish geometry by comparisons with theoretical dipolar lineshapes (Figure 15).

Figure 14 Synchronously sampled time domain ^{13}C signal of a ^{19}F , ^{15}N , ^{13}C -triple-labeled emerimicin diluted by natural-abundance peptide. The ^{15}N TEDOR-selected ^{13}C signal is sampled once each rotor period either with (S) or without (S_0) ^{19}F dephasing pulses. Magic angle spinning was at 5 kHz

Figure 15 Dipolar spectra obtained by Fourier transforms of time domain simulations performed as described in the caption to Figure 13. The widths of both dipolar spectra are determined by the 100-Hz $S-X$ coupling. Details of the lineshape are determined by orientation of $I-S$ and $S-X$ dipolar tensors

1 INTRODUCTION

While solution NMR methods have been successfully applied for elucidating three dimensional (3D) structures of molecules including proteins (see **Biological Macromolecules: Structure Determination in Solution**, Volume 2), solid-state NMR has not attained such a stage. This review demonstrates the state of the art of structural determination of a whole molecule by solid state NMR, which should be complementary to solution NMR and irreplaceable for insoluble systems. In NMR of solids, measurements of dipolar interactions provide direct information on geometrical structures; they are most conveniently made under magic angle spinning (MAS) (see **Magic Angle Spinning**, Volume 5) with hidden potential of determining more than one distance using a single sample. However, most of the methods developed so far are of non-selective measurements of dipolar couplings, by which it is difficult to deduce quantitative structural information when more than two spins are involved. Hence, only one specific internuclear distance or dihedral angle is commonly determined by selectively isotope-labeling a particular pair of atoms. Then, many doubly-labeled samples must be prepared, if one tries to determine the 3D structure composed of sizable atoms by such non-selective approaches. On the other hand, if a specific dipolar interaction in a multiply or uniformly labeled system can selectively be recoupled, all the structural parameters necessary to determine the 3D structure can be obtained one by one using a single sample, significantly saving labor for sample preparation.

To achieve frequency-selective recoupling, it is required to remove all dipolar couplings at once, and recouple a

specific pair. Using MAS, one can remove all the dipolar couplings together with chemical shift anisotropies under proton decoupling, and therefore the remaining problem is to achieve selective recoupling under MAS fast enough to remove all the other dipolar interactions simultaneously. For homonuclear dipolar interactions, rotational resonance (R^2)¹⁻⁸ has been developed as a simple selective recoupling method, and in fact, has been applied to biologically interesting molecules.⁹ In the R^2 method, selection of a pair of spins is made by adjusting an integral multiple of the MAS frequency ν_R to the difference of the chemical shifts of the two spins. Therefore, R^2 is frequency-difference selective, and if more than one spin pair with the same separation exists, they are simultaneously recoupled. Further, when the chemical shift difference for the two spins is relatively small, the MAS frequency must be lowered, leading to imperfect decoupling of the other dipolar interactions.

Selective recoupling among homonuclear spins can also be achieved in a tilted rotating frame.¹⁰ Under rf irradiation, the Zeeman interaction for a spin system can be written in a tilted rotating frame (X, Y, Z) as

$$\frac{\mathcal{H}}{\text{Hz}} = \sum_i \nu_{ei} \hat{I}_{Zi} \quad (1)$$

while the conventional Zeeman interaction in the rotating frame (x, y, z) is written as

$$\mathcal{H} = \sum_i \Delta \nu_i \hat{I}_{zi} \quad (2)$$

where ν_e denotes the effective field and $\Delta \nu$ is the resonance offset. By comparing these two equations, it may be expected that the R^2 condition in the rotating frame:

$$|\Delta \nu_1 - \Delta \nu_2| = n \nu_R \quad (3)$$

would be modified in the tilted rotating frame as

$$|\nu_{e1} - \nu_{e2}| = n \nu_R \quad (4)$$

In fact, this is one of the recoupling conditions in the tilted rotating frame. There are additional recoupling conditions, namely, $\nu_{e1} + \nu_{e2} = n \nu_R$ and $\nu_{eX} = n \nu_R$ ($X = I$ or S), as derived in the following section. These conditions are referred to as the R2TR (rotational resonance in the tilted rotating frame) conditions. There are three adjustable parameters to achieve one of the R2TR conditions, namely, the intensity ν_1 and the frequency ν of the rf irradiation and the MAS frequency ν_R . This diversity makes it possible to find an R2TR condition even for a pair of spins with a small chemical shift difference without relaxing the fast MAS condition necessary for decoupling all other dipolar couplings. Further, it should be pointed out here that, while R^2 is frequency-difference selective, R2TR is frequency selective. Hence, a particular dipolar coupling can be recoupled by properly choosing the experimental parameters even when more than two lines have equal chemical-shift differences.

2 THEORY

First, we briefly touch upon rotational resonance recoupling. A dipolar-coupled homonuclear two-spin $I-S$ system in a

rotating powdered sample is considered. For simplicity, the chemical shift anisotropies (CSAs) are neglected. The total spin Hamiltonian can be written as

$$\mathcal{H} = \Delta\nu_I \hat{I}_z + \Delta\nu_S \hat{S}_z + \mathcal{H}_D(t) \quad (5)$$

where $\mathcal{H}_D(t)$ is the homonuclear dipolar interaction

$$\mathcal{H}_D(t) = D(t) \left\{ \hat{I}_z \hat{S}_z - \frac{1}{4} (\hat{I}_+ \hat{S}_- + \hat{I}_- \hat{S}_+) \right\} \quad (6)$$

with the spatial part modulated by MAS

$$D(t) = \sum_{n=\pm 1, \pm 2} \nu_{Dn} \exp(in\nu_R t) \quad (7)$$

Here, ν_{Dn} is a function of the internuclear distance and the polar angles defining the direction of the $I-S$ vector in a rotor-fixed frame. $\mathcal{H}_D(t)$ is transferred into the frame of the Zeeman interaction by using the unitary operator

$$U(t) = \exp(i\Delta\nu_I \hat{I}_z t) \exp(i\Delta\nu_S \hat{S}_z t) \quad (8)$$

as

$$\begin{aligned} \widetilde{\mathcal{H}}_D(t) &= U(t) \mathcal{H}_D(t) U^{-1}(t) \\ &= \sum_{n=\pm 1, \pm 2} \nu_{Dn} \left[\hat{I}_z \hat{S}_z \exp(in\nu_R t) \right. \\ &\quad \left. - \frac{1}{4} (\hat{I}_+ \hat{S}_- + \hat{I}_- \hat{S}_+) \exp\{i(n\nu_R - \Delta)t\} \right] \end{aligned} \quad (9)$$

where Δ is the difference of the isotropic chemical shift: $\Delta = \nu_I - \nu_S$. This equation shows that the rotational resonance recoupling occurs at $\Delta = n\nu_R$ with $n = \pm 1, \pm 2$. If one takes account of the chemical shift anisotropies, one can prove that recoupling occurs even under higher-order ($|n| > 2$) conditions.⁴

Second, we examine the effect of continuous wave rf irradiation along the x -axis of the rotating frame for the two-spin system. The total Hamiltonian

$$\mathcal{H} = \Delta\nu_I \hat{I}_z + \Delta\nu_S \hat{S}_z + \nu_1 (\hat{I}_x + \hat{S}_x) + \mathcal{H}_D(t) \quad (10)$$

is transformed into the tilted rotating frame (X, Y, Z) by the unitary transformation of

$$U_{TR} = \exp(i\beta_I \hat{I}_y) \exp(i\beta_S \hat{S}_y) \quad (11)$$

where β_X denotes the angle between the z -axis of the rotating frame (i.e., the direction of the static field) and the Z -axis of the tilted rotating frame (i.e., the direction of the effective field) for the X spin. The total spin Hamiltonian in the tilted rotating frame can be given by

$$\begin{aligned} \mathcal{H}^{TR} &= U_{TR} \mathcal{H} U_{TR}^{-1} \\ &= \nu_{eI} \hat{I}_Z + \nu_{eS} \hat{S}_Z + U_{TR} \mathcal{H}_D(t) U_{TR}^{-1} \end{aligned} \quad (12)$$

where ν_{eX} denotes the strength of the effective field for the X spin. This is further transferred into the interaction frame using the following unitary operator

$$U_{\text{eff}}(t) = \exp(i\nu_{eI} \hat{I}_Z t) \exp(i\nu_{eS} \hat{S}_Z t) \quad (13)$$

and the result is

$$\begin{aligned} \mathcal{H}_D^*(t) &= U_{\text{eff}}(t) U_{TR} \mathcal{H}_D(t) U_{TR}^{-1} U_{\text{eff}}^{-1}(t) \\ &= \sum_{n=\pm 1, \pm 2} \nu_{Dn} [A \hat{I}_Z \hat{S}_Z \exp(-in\nu_R t) \\ &\quad + B[\hat{I}_+ \hat{S}_- \exp\{i(n\nu_R + \Delta_{\text{eff}})t\} \\ &\quad + \hat{I}_- \hat{S}_+ \exp\{i(n\nu_R - \Delta_{\text{eff}})t\}] \\ &\quad + R[\hat{I}_Z \hat{S}_+ \exp\{i(n\nu_R + \nu_{eS})t\} \\ &\quad + \hat{I}_Z \hat{S}_- \exp\{i(n\nu_R - \nu_{eS})t\}] \\ &\quad + S[\hat{I}_+ \hat{S}_Z \exp\{i(n\nu_R + \nu_{eI})t\} \\ &\quad + \hat{I}_- \hat{S}_Z \exp\{i(n\nu_R - \nu_{eI})t\}] \\ &\quad + Q[\hat{I}_+ \hat{S}_+ \exp\{i(n\nu_R + \Sigma_{\text{eff}})t\} \\ &\quad + \hat{I}_- \hat{S}_- \exp\{i(n\nu_R - \Sigma_{\text{eff}})t\}]] \end{aligned} \quad (14)$$

where the coefficients A , B , R , S , and Q are functions of the angle β_X , whose explicit forms are found in Ref.¹¹. It can be shown that the spatial part of $\mathcal{H}_D^*(t)$ is modulated by MAS with the spinning frequency ν_R and $2\nu_R$, while the spin part is modulated by the effective field with the frequencies of $\Sigma_{\text{eff}} = \nu_{eI} + \nu_{eS}$, $\Delta_{\text{eff}} = \nu_{eI} - \nu_{eS}$, ν_{eI} , and ν_{eS} . When any of the conditions Σ_{eff} , Δ_{eff} , ν_{eI} , or $\nu_{eS} = m\nu_R$ ($m = \pm 1$ or ± 2) is met, the time dependence of the spatial part and the spin part in $\mathcal{H}_D^*(t)$ is partially canceled with each other to give a static dipolar interaction $\overline{\mathcal{H}}_D^*$.

3 METHOD

Determination of the 3D structure of a multiply labeled molecule can be accomplished by obtaining all bond lengths, bond angles, and dihedral angles. For a peptide, however, one may use typical bond lengths and angles because they differ only slightly among peptides, and the peptide 3D structure can be constructed by determining dihedral angles.

Figure 1 illustrates the strategy. For a multiply $^{13}\text{C}/^{15}\text{N}$ labeled peptide, all dipolar interactions are removed uniformly by fast MAS and proton decoupling. Then, a specific three-bonds distant pair of spins is selectively recoupled by applying an rf field satisfying a proper R2TR condition. The time development of the magnetization of either of the paired spins is measured, from which the corresponding dihedral angle is deduced. This procedure is repeated for other spin pairs, until all the dihedral angles are determined.

The pulse sequence for the selective recoupling experiments is shown in Figure 2(a). During the recoupling period (t_m), the rf field satisfying a R2TR condition $\nu_{eI} + \nu_{eS} = \nu_R$ is applied to one of the paired spins concerned. This rf field also functions for spin-locking the magnetization. Then, the t_m dependence of the spin-locked magnetization is monitored after removing the possible small y component of the magnetization by applying a 90_X° pulse. The t_m dependence of the magnetization is also affected by $T_{1\rho}$ relaxation. Measuring $T_{1\rho}$ under the same irradiation condition but with a slightly (~ 500 Hz) different spinning frequency so as not to satisfy the DQ R2TR condition, we can remove the relaxation effect from the t_m dependence by multiplying it by $\exp(t_m/T_{1\rho})$.

Figure 1 Schematic illustration of uniform decoupling by MAS and selective recoupling

The other conditions of ZQ, SQ, and DQ ($n > 1$) are not suitable for the present experiments for the following reasons. First, to satisfy a ZQ condition, the chemical shift difference between a specific pair of spins must be larger than ν_R . However, chemical shift differences of ^{13}C or ^{15}N spin pairs at a common magnetic-field intensity are not so large as to satisfy a ZQ condition for ν_R fast enough to completely decouple the other dipolar couplings. Second, under a SQ condition, both chemical shift anisotropies (CSAs) of the relevant carbons are dominantly recovered, obscuring the effect of dipolar recoupling. Last, a DQ condition with $n > 1$, which requires a large rf-field intensity for ν_R fast enough to decouple the other dipolar couplings, lowers the selectivity of recoupling.

The influence of intermolecular dipolar couplings on the dipolar recoupling experiments was reduced by diluting a uniformly labeled sample (10%) with natural abundance material (90%). In the recoupling-time dependence experiments for the 10% uniformly labeled sample, 10% of the signal intensity at $t_m = 0$ was subtracted from the intensity observed at each recoupling time t_m , because it was found that the magnetization of the natural abundance material is kept almost constant during t_m .

An alternative approach to determine a dihedral angle is to measure mutual orientations of two or more anisotropic spin interactions. In the R2TR method, one can easily and quickly switch the dipolar interaction to be recoupled from one to another by changing ν and ν_1 under a constant spinning speed contrary to the normal R^2 method. This makes it possible to realize a 2D experiment which correlates the AB and CD dipolar powder patterns in an A–B–C–D ^{13}C

Figure 2 Pulse sequences to determine dihedral angles. (a) Dipolar recoupling experiment. After CP, a rf field satisfying a DQ condition for a particular pair of ^{13}C spins is applied on resonance to one of the spins for a recoupling time t_m . Then, the transverse magnetization of the spin is observed as a function of t_m . (b) 2D dipolar correlation experiment. After CP, the C magnetization in a four ^{13}C spin (A–B–C–D) system is suppressed by a DANTE pulse train. The A–B and the C–D dipolar interactions are selectively recovered in the t_1 and t_2 periods, respectively. These dipolar powder patterns are correlated by transferring magnetization from A or B to C or D in the mixing period. The AB/CD dipolar correlation spectrum is obtained by observing the C magnetization in the detection period t_3 . (Reproduced from Nomura et al.¹³ with kind permission from Kluwer Academic Publishers)

spin system. Figure 2(b) shows the pulse sequence for the 2D dipolar correlation experiment. After cross polarization (CP), the C magnetization is suppressed by a selective 90° (DANTE) pulse followed by a dephasing period (t_d). In the first evolution period (t_1) the AB dipolar interaction is selectively recoupled, in the mixing period the A or B magnetization is selectively transferred to the C or D spin, and in the second evolution period (t_2) the C magnetization evolves under the selectively recoupled CD dipolar interaction. The AB/CD dipolar correlated 2D powder pattern is selectively obtained by observing the C spin in the detection period (t_3).

Recoupling may take place even in off-R2TR conditions to some extent, making the selectivity incomplete. The incompleteness of selectivity can be taken into account by including several spins into simulations in addition to the relevant two spins. To examine selectivity, we studied magnetization transfer in uniformly ^{13}C labeled L-alanine.¹¹ Figure 3(a) shows the ^{13}C 2D exchange NMR spectrum observed without applying any ^{13}C rf field during a mixing time of 4 ms under a MAS frequency of 5718 Hz. No conventional R^2 effects were observed at this spinning speed. The spectrum in Figure 3(b)

Figure 3 ^{13}C 2D exchange NMR spectra of uniformly ^{13}C labeled L-alanine. It was observed (a) without and (b) with applying a ^{13}C rf field during a mixing time of 4 ms under the MAS frequency of 5718 Hz. The rf field with the intensity of 4 kHz was applied at 296.7 ppm for the spectrum (b) to satisfy a R2TR condition $\Delta_{\text{eff}} = 2\nu_{\text{R}}$ for the carboxyl and the methyl carbons

was obtained at the same spinning speed while applying an rf field with the intensity of 4 kHz during the same mixing time to satisfy the ZQ R2TR condition $\Delta_{\text{eff}} = 2\nu_{\text{R}}$ for the carboxyl and methyl ^{13}C spins. Cross peaks appear between the carboxyl and methyl carbons, but no cross peaks can be seen between the carboxyl and methine carbons or between the methine and methyl carbons. This result confirms that the dipolar interaction between the carboxyl and the methyl carbons can be selectively recovered by the R2TR experiment, in spite of the fact that the recoupled dipolar coupling is below one fourth the other couplings. The stronger couplings remain completely decoupled by MAS.

Figure 4 shows the observed and the calculated mixing-time dependence of the individual ^{13}C magnetizations after saturation of the methyl carbon signal. The initial rapid oscillation of the carboxyl ^{13}C magnetization can be ascribed to the spinning sidebands in the tilted rotating frame,¹¹ which is damped quickly within a few milliseconds due to rf-field inhomogeneity. Hence, in the following, this oscillation in the simulation was damped to the same extent as the experimental data. Except for this initial oscillation and slight decay due to relaxation, the sum of the ^{13}C magnetizations of the carboxyl and the methyl carbons, $M_{0I} + M_{0S}$, is shown to be conserved. Further, the observed and the calculated curves for the methine carbon in Figure 4(b) again shows that the polarization transfer occurs selectively between the carboxyl and the methyl carbons, and further that a mixing time of 5 ms is enough for the polarization transfer between two carbons separated by 0.25 nm.

Further, to examine how large the chemical shift difference between non-relevant spins should be to achieve high selectivity, several isotropic chemical-shift values were assumed for the methine carbon, keeping its chemical shift anisotropy constant. Figure 5 shows the calculated mixing-time dependence of the methine ^{13}C magnetization for four chemical shift differences between the methyl and the methine carbons: 0, 500, 1000, and 2340 Hz. From Figure 5, it can be concluded that the chemical shift difference should be larger than 1000 Hz for selective transfer, leading to the following practical criteria of spins being added in simulations: For the selective recoupling experiment of A and D in a A–B–C–D ^{13}C system with observing the D magnetization, not only all the four spins, but also the following ^{13}C spin(s), if any: ^{13}C directly bonded to D (A), and ^{13}C within about 0.25 nm from D (A)

with the ν_{e} difference between the ^{13}C and A (D) less than 1000 Hz.

4 APPLICATION TO GLYCYLISOLEUCINE

In the following, the complete 3D structure of a glycyloisoleucine (Gly-Ile) molecule by R2TR is determined using a powder sample of uniformly ^{13}C , ^{15}N -labeled Gly-Ile molecules, including all the positions of carbons, nitrogens, and oxygens in both main and side chains.^{12,13} The 3D structure of a Gly-Ile molecule is obtained by measuring the six dihedral angles shown in Figure 6. In this study, ψ_{G} , ω_{G} , ϕ_{I} , χ_{I1} , and χ_{I2} are defined as dihedral angles $\text{N}_{\text{G}}-\text{C}_{\text{G}}^{\alpha}-\text{C}_{\text{G}}^{\beta}-\text{N}_{\text{I}}$, $\text{C}_{\text{G}}^{\alpha}-\text{C}_{\text{G}}^{\beta}-\text{N}_{\text{I}}-\text{C}_{\text{I}}^{\alpha}$, $\text{C}_{\text{G}}^{\beta}-\text{N}_{\text{I}}-\text{C}_{\text{I}}^{\alpha}-\text{C}_{\text{I}}^{\beta}$, $\text{C}_{\text{I}}^{\alpha}-\text{C}_{\text{I}}^{\beta}-\text{C}_{\text{I}}^{\gamma 1}-\text{C}_{\text{I}}^{\delta}$, and $\text{C}_{\text{I}}^{\alpha}-\text{C}_{\text{I}}^{\beta}-\text{C}_{\text{I}}^{\gamma 1}-\text{C}_{\text{I}}^{\delta}$, respectively, by taking zero degrees for the *cis* conformation. ψ_{I} is defined as the angle between the $\text{N}_{\text{I}}-\text{C}_{\text{I}}^{\alpha}$ bond and the $\text{O}_{\text{I}}^1-\text{C}_{\text{I}}^{\gamma 1}-\text{O}_{\text{I}}^2$ plane, being between 0 and 180°. ψ_{G} , ω_{G} , ϕ_{I} , and χ_{I1} were determined by performing the R2TR dipolar recoupling experiment for a proper three or four-bonds distant spin pair, and χ_{I2} by a 2D dipolar correlation experiment because of the reason mentioned later, assuming the typical bond lengths and angles shown in Figure 6. The planar configuration of the peptide plane was also assumed.

Although the CSA interaction was neglected in Theory for simplicity, it does contribute to the results, and should thus be included into numerical calculations. Especially, the contribution of the CSA tensors for carbonyl carbons and amide nitrogens in the main chain are important owing to their large anisotropies (see **Chemical Shift Tensors**, Volume 2). However, the CSA tensors for carbonyl carbons are not very different from peptide to peptide. Hence, the mean values of δ and η for the carbonyl carbon tensors reported for some peptides are adopted (Table 1). For the directions of the principal axes, it is generally observed that the σ_{33} axis is perpendicular to the sp^2 plane.¹⁴ On the other hand, the σ_{22} axis may make a small angle with the C=O bond direction. For $\text{C}_{\text{G}}^{\beta}$, the σ_{33} axis is assumed to be perpendicular to the sp^2 plane and the σ_{22} axis makes the angle of 4.5° with the $\text{C}_{\text{G}}^{\beta}-\text{O}_{\text{G}}$ bond toward the $\text{C}_{\text{G}}^{\beta}-\text{C}_{\text{G}}^{\alpha}$ bond.¹⁵ For $\text{C}_{\text{I}}^{\alpha}$, the σ_{33} axis is perpendicular to the sp^2 plane and the σ_{11} axis is along the $\text{C}_{\text{I}}^{\alpha}-\text{C}_{\text{I}}^{\beta}$ bond. The δ and η values for N_{I} and N_{G} were

Figure 4 Experimental (○) and simulated (—) mixing-time dependence of the normalized magnetizations of (a) the carboxyl, (b) the methine, and (c) the methyl carbons under the condition $\Delta_{\text{eff}} = 2\nu_R$ satisfied between the carboxyl and the methyl carbons after saturation of the methyl carbon signal. The experiments were performed with the same parameters as described in the caption of Figure 3, excluding the initial magnetization for the methyl carbon. (Reproduced from Takegoshi et al.¹¹ with kind permission from Academic Press)

determined from spinning side bands observed at a low speed. The σ_{22} axis for N_I is assumed to be perpendicular to the peptide plane and the σ_{11} axis is along the N–C=O bond.¹⁶ For N_G , the σ_{33} direction is along the N_G – C_G^α bond direction and the σ_{11} axis is perpendicular to the N_G – C_G^α – C_G' plane.¹⁶ For the aliphatic carbons, it will be shown that the CSA interactions do not significantly affect simulated results. The ^{13}C and ^{15}N chemical shift parameters used for numerical simulations are collected in Table 1.

Figure 7 shows a ^{13}C COSY spectrum observed at $\nu_R = 17.5$ kHz under TPPM decoupling, presenting the connectivity between the observed eight signals (C_1 – C_8) splitted by the

Figure 5 Simulated mixing-time dependence of the methine carbon magnetization under the same conditions as described in the caption of Figure 4, excluding the isotropic chemical shift of the methine carbon. The assumed chemical shift relative to the methyl carbon is: (a) 0 Hz, (b) 500 Hz, (c) 1000 Hz, and (d) 2340 Hz

^{13}C – ^{13}C spin–spin couplings. From the connectivity and common knowledge of ^{13}C chemical shifts, all the signals can straightforwardly be assigned as $C_2 = C_G'$, $C_4 = C_G^\alpha$, $C_1 = C_1'$, $C_3 = C_1^\alpha$, $C_5 = C_1^\beta$, $C_6 = C_1^{\gamma 1}$, $C_7 = C_1^{\gamma 2}$, and $C_8 = C_1^\delta$. The observed isotropic chemical shifts are collected in Table 1.

Firstly, determination of the main-chain structure, which is described by dihedral angles conventionally named as ψ , ω , and ϕ (Figure 6), is discussed. ψ_G was determined by the selective-recoupling experiment of N_G and N_I . For the selective recoupling, an rf field with the intensity of 8300 Hz was applied on resonance to N_G , which satisfies a DQ condition under $\nu_R = 17.5$ kHz, and the recoupling-time dependence of the spin-locked magnetization of N_G was observed (Figure 8a). ψ_G was determined to be 180° from the root-mean-square deviation (RMSD) between the experimental data and the curves calculated for various ψ_G (Figure 8b). Let us examine to what extent the assumptions for the chemical shift tensors lead to error for determination of ψ_G . It was found that a deviation of 10° in the σ_{11} direction for N_I from the peptide bond direction to the N– C_α direction hardly changes the simulation curve. The deviation of 10° in the σ_{33} axis for N_G from the C_G^α – N_G bond direction does not change it either. The averages of the CSA parameters of the amide nitrogens¹⁶ in AcGlyGlyNH₂, AcGlyAlaNH₂, AcGlyTyrNH₂, and GlyGly·HCl gives $(\delta, \eta) = (103.2 \text{ ppm}, 0.22)$, which are similar to the observed ones, leads to the same ψ_G value of 180° as above. It should be pointed out, however, that changing the observed CSA parameters of N_I to those for the amide nitrogen in AcGlyTyrNH₂ $((\delta, \eta) = (96.4 \text{ ppm}, 0.26))$ or GlyGly·HCl $((\delta, \eta) = (101.0 \text{ ppm}, 0.02))$ ¹⁶ results in the best-fit values of $\psi_G = \pm 154$ or $\pm 159^\circ$, respectively. Such sensitivity of the recoupling-time dependence to the CSA parameters δ and η would be found particularly around $\psi = 180^\circ$ at which the ^{15}N – ^{15}N dipolar interaction becomes the weakest and thus insensitive to the dihedral angle. Nevertheless, the plot of $\Delta\chi^2$ shown in Figure 8(b) indicates that the 68% confidence interval ($\Delta\chi^2 < 1$) is still $\pm 10^\circ$. For a better precision, it is desirable to measure the CSA parameters of amide nitrogens and use them in the simulations for determining ψ .

Figure 7 ^{13}C COSY spectrum of uniformly $^{13}\text{C},^{15}\text{N}$ -labeled glycyloisoleucine. It was obtained under the spinning speed of 17.5 kHz and TPPM decoupling. (Reproduced from Nomura et al.¹³ with kind permission from Kluwer Academic Publishers)

however, be pointed out that ϕ_1 is precisely determined but ψ_1 is not. This is because the dipolar coupling directly contributes to the determination of ϕ_1 , but ψ_1 is obtained only through the relative orientation of the C'_1 CSA tensor to the other tensors. Therefore, the validity of the use of the CSA tensors assumed for C'_G and C'_1 in the above simulations should be examined.

First, as for C'_G , the experimental result was simulated using the CSA parameters and orientations determined for AcGlyGlyNH₂, AcGlyAlaNH₂, AcGlyTyrNH₂, and GlyGly·HCl.¹⁵ The best-fit values of (ϕ_1, ψ_1) do not deviate significantly for the four sets of parameters ($-71^\circ \sim -78^\circ$, $139^\circ \sim 148^\circ$). As for the tensor orientation of C'_1 , it was assumed that σ_{11} is parallel to the $\text{C}'_1\text{--C}'_1$ bond, while it may deviate from the bond direction by about 10° .¹⁴ It was found that the 10° deviation leads to $(\phi_1, \psi_1) = (-76^\circ, 138^\circ)$. For the CSA parameters (δ, η) , the values for glycine,¹⁷ L-alanine,¹⁸ L-serine,¹⁹ L-threonine,²⁰ and L-asparagine²¹ were used to find (ϕ_1, ψ_1) to be $(-75^\circ \sim -76^\circ, 137^\circ \sim 150^\circ)$.

These results show that the use of likely CSA tensors for C'_G and C'_1 in the simulations causes only a small error in the determination of ϕ_1 , but leads to a considerable error in ψ_1 . This is also because the ϕ_1 value is directly related to the distance, while the ψ_1 value is related mainly to the relative orientations of the CSA tensors, being more sensitive to them. To obtain a more precise value for ψ_1 , (δ, η) for C'_1 should be measured by some method.

The present result of the recoupling experiment for C'_G and C'_1 indicates that one dipolar recoupling experiment per amino acid residue is enough to determine dihedral angles (ψ, ω, ϕ) which provide the 3D backbone structure of a peptide. In the above, however, $\omega_G = 180^\circ$ was assumed, while in cyclic peptides or peptides with proline, ω_G may be 0° . Hence, the possibility of determining whether $\omega_G = 0^\circ$ or 180° was examined. The dotted line in Figure 9(a) shows

Figure 8 (a) Recoupling-time dependence of the normalized magnetization of N_G in 10% uniformly $^{13}\text{C},^{15}\text{N}$ -labeled glycyloisoleucine. The dipolar recoupling experiment was carried out using the pulse sequence in Figure 2(a) under a R2TR condition ($\nu_{eI} + \nu_{eS} = \nu_R$) satisfied for N_G and N_I by applying a rf field with the intensity of 8300 Hz on resonance to N_G under MAS with $\nu_R = 17.5$ kHz. Experimental points are shown by circles. The standard deviation for each point is ca. ± 0.05 . The curves are calculated for the dihedral angle ψ_G of 180° . $T_{1\rho}$ was determined to be 70 ms by an off-R2TR experiment, and used to remove the relaxation effect from the dipolar recoupling data. (b) Dihedral angle (ψ_G) dependence of RMSD (---) between the experimental (Figure 8a) and simulated data and of $\Delta\chi^2$ (—). (Reproduced from Nomura et al.¹³ with kind permission from Kluwer Academic Publishers)

the curve simulated with $\omega_G = 0^\circ$ and the best-fit values of $(\phi_1, \psi_1) = (-86^\circ, 167^\circ)$, showing that it is difficult to determine the difference between the two possibilities $\omega_G = 0^\circ$ and $\omega_G = 180^\circ$ by this experiment. Therefore, another recoupling experiment was made for C'_G and C'_1 , by applying an rf field with an intensity of 2800 Hz on resonance to the C'_1 carbon which satisfies a DQ condition under spinning with $\nu_R = 17.03$ kHz. Figure 10 shows the recoupling-time dependence of the magnetization of C'_1 together with the simulated curves obtained for the two sets of $(\omega_G, \phi_1, \psi_1)$, namely, $(180^\circ, -76^\circ, 147^\circ)$ and $(0^\circ, -86^\circ, 167^\circ)$. Clearly, the former set reproduces the observation as expected. It indicates that even when one does not know whether $\omega = 0^\circ$ or 180° , one can determine the three dihedral angles (ψ, ω, ϕ) by two dipolar recoupling experiments per amino acid residue.

Figure 9 (a) Recoupling-time dependence of the normalized magnetization of C'_1 in 10% uniformly ^{13}C , ^{15}N -labeled glycylisoleucine. The dipolar recoupling experiment was carried out using the pulse sequence in Figure 2(a) under a R2TR condition ($\nu_{eI} + \nu_{eS} = \nu_R$) satisfied for C'_1 and C'_G by applying a rf field with the intensity of 8500 Hz on resonance to the C'_1 carbon under MAS with $\nu_R = 17.054$ kHz. Experimental points are shown by circles. The standard deviation for each point is ca. ± 0.03 . The solid line is the curve calculated for the dihedral angles $(\omega_G, \phi_1, \psi_1) = (180^\circ, -76^\circ, 147^\circ)$, whereas the dotted line for $(\omega_G, \phi_1, \psi_1) = (0^\circ, -86^\circ, 167^\circ)$. $T_{1\rho}$ was determined to be 500 ms for C'_1 in 10% uniformly ^{13}C , ^{15}N -labeled glycylisoleucine, and used to correct the experimental data. (b) The contour plot of RMSD between the experimental spectrum (Figure 5a) and the simulations for various sets of (ϕ_1, ψ_1) and $\omega_G = 180^\circ$. The global minimum is indicated by a dot. (c) Dihedral angles $(\phi_1$ and $\psi_1)$ dependence of $\Delta\chi^2$ for $\omega_G = 180^\circ$. (Reproduced from Nomura et al.¹³ with kind permission from Kluwer Academic Publishers)

As exemplified here, the recoupling-time behavior in a general $\text{sp}^2\text{--sp}^2$ ^{13}C spin pair depends not only on the internuclear distance, but also on the relative orientations between the CSA tensors and the dipolar vector as well as the CSA parameters. Owing to the dependence caused by CSA, the magnitudes of not only ϕ but also ψ can be determined. Moreover, a few more carbons also contribute to the experimental result due to the incomplete selectivity; however, it provides the benefit of being able to determine the signs of ϕ and ψ . While the contribution of CSA tensors and other spins makes the simulation troublesome and somewhat reduces the accuracy in determination of dihedral angles, it provides information which cannot easily be obtained by other means.

As described above, the dihedral angles for the main chain were determined. The dihedral angles for the side chain in the isoleucine residue can also be determined in a similar manner. However, since their chemical-shift values are very similar to each other and moreover the atomic positions are close to each other, selective recoupling of one of these pairs is indeed difficult. In this sense, the isoleucine residue is one of the most demanding ones for the present approach.

The χ_{II} angle was obtained by selective dipolar recoupling between C'_1 and $C_1^{\gamma 1}$, which was attained by applying a rf field with the intensity of 2000 Hz on resonance to the C'_1 carbon under MAS with $\nu_R = 17.46$ kHz. In the simulation, C_1^α , C_1^β , and C_1^δ besides C'_1 and $C_1^{\gamma 1}$ were included, and χ_{II} was determined to be 178° . The effect of the chemical shift tensors of C'_1 on the χ_{II} value were examined using the literature (δ, η) values of C' in L-alanine, L-serine, L-threonine, and L-asparagine, and it was found that the best-fit values of χ_{II} are virtually unaffected ($175^\circ \sim 178^\circ$). Also, changing the CSA parameters for $C_1^{\gamma 1}$ to those determined for the α -methylene carbon of *n*-eicosane²³ provides essentially the same value of $\chi_{\text{II}} = -176^\circ$.

As exemplified by the present case, in a general $\text{sp}^3\text{--sp}^2$ ^{13}C spin pair, possible variations of the parameters and orientations of their CSA tensors barely affects the recoupling-time dependence. Thus, likely CSA parameters (δ, η) and tensor orientations for both carbons may be used safely.

To determine the χ_{I2} angle in the same way as above, it is necessary to selectively recouple C_1^α and C_1^δ , or $C_1^{\gamma 2}$ and C_1^δ . Due to the spectral congestion, it is difficult to find a R2TR

Figure 10 Recoupling-time dependence of the normalized magnetization of C_1' in 10% uniformly $^{13}\text{C},^{15}\text{N}$ -labeled glycylisoleucine. The dipolar recoupling experiment was carried out using the pulse sequence in Figure 2(a) under a R2TR condition ($\nu_{eI} + \nu_{eS} = \nu_R$) satisfied for C_1' and C_1^α by applying a rf field with the intensity of 2800 Hz on resonance to the C_1' carbon under MAS with $\nu_R = 17.03$ kHz. Experimental points are shown by circles. The standard deviation for each point is ca. ± 0.04 . The solid line is the curve calculated for the dihedral angles $(\omega_G, \phi_1, \psi_1) = (180^\circ, -76^\circ, 147^\circ)$, whereas the dotted line for $(\omega_G, \phi_1, \psi_1) = (0^\circ, -86^\circ, 167^\circ)$. $T_{1\rho}$ was determined to be 500 ms for C_1' in 10% $^{13}\text{C},^{15}\text{N}$ -labeled glycylisoleucine, and used to correct the experimental data. (Reproduced from Nomura et al.¹³ with kind permission from Kluwer Academic Publishers)

condition suitable for these pairs. Therefore, a $C_1^\alpha - C_1^\beta / C_1^{\gamma 1} - C_1^\delta$ dipolar correlation 2D powder pattern was observed using the sequence shown in Figure 2(b). In this experiment, a 100% uniformly labeled sample was used for obtaining a high signal-to-noise ratio. The use of the undiluted sample is justified, because the dipolar interactions recoupled in the t_1 and t_2 periods are of directly bonded ones, and thus much stronger than the intermolecular dipolar interactions.

The spinning speed ν_R was set to 5110 Hz, satisfying the R^2 condition for C_1^δ and C_1^α . In the t_1 period, a DQ condition is matched for $C_1^{\gamma 1}$ and C_1^δ by applying an rf field with an intensity of 2540 Hz on resonance to C_1^δ . During the mixing time t_m , the magnetization of C_1^δ is selectively transferred to C_1^α by R^2 . In the t_2 period, a DQ condition is fulfilled for C_1^α and C_1^β by applying an rf field with an intensity of 1825 Hz on resonance to C_1^α . Figure 11(a) compares the experimental and the simulated 2D spectra, while Figure 11(b) shows the χ_{12} dependence of RMSD between the experimental and calculated 2D spectra. Even though the agreement is not excellent, the $\Delta\chi^2$ plot in Figure 11(b) shows that the 68% confidence interval is $\pm 5^\circ$, and χ_{12} was determined to be 160° . The sign of χ_{12} cannot be determined from this experiment. The dihedral angle $(C_1^{\gamma 2} - C_1^\beta - C_1^{\gamma 1} - C_1^\delta)$ was calculated to be 39° from $\chi_{12} = -160^\circ$, and to be 79° from $\chi_{12} = 160^\circ$; it suggests that the steric hindrance between the two methyl groups is smaller for the latter case. Therefore, the positive sign was preferred.

In the simulation, $C_1^{\gamma 2}$ in addition to C_1^α , C_1^β , $C_1^{\gamma 1}$, and C_1^δ were included, and a somewhat long $C_1^{\gamma 1} - C_1^\delta$ bond length of

Figure 11 (a) The 2D $C_1^\alpha - C_1^\delta / C_1^{\gamma 1} - C_1^\delta$ dipolar correlation spectrum for uniformly $^{13}\text{C},^{15}\text{N}$ -labeled glycylisoleucine. The experiment was performed using the pulse sequence in Figure 2(b). The spinning frequency ν_R is 5110 Hz. The ^{13}C rf-field intensities during the t_1 period, the mixing time, and the t_2 period are $\nu_1 = 2540$ (on resonance to the C_1^δ carbon), 0, and 1825 Hz (on resonance to the C_1^α carbon), respectively. (left) Experimental 2D spectrum. (right) Simulated 2D spectrum calculated for the $C_1^{\gamma 1} - C_1^\delta$ distance of 1.62 Å and the dihedral angle χ_{12} of 160° . The contour lines are plotted at 65, 77, and 88% of the maximum intensity. (b) Dihedral angle (χ_{12}) dependence of RMSD (---) between the experimental (Figure 11a) and simulated 2D dipolar correlation spectra and of $\Delta\chi^2$ (—). (Reproduced from Nomura et al.¹³ with kind permission from Kluwer Academic Publishers)

1.62 Å had to be assumed for the best fitting. This unusual bond length was attributed to a thermal vibration of C_1^δ . It is worthy to be noted that with the existence of molecular motion, dihedral angles cannot be correctly determined from distance measurements. However, in a theoretical study of vibrational effects,²⁴ it has been proved that the dipolar 2D powder patterns provide correct dihedral angles even under the presence of molecular vibrations as long as the asymmetry of the vibration is negligible. It is a common problem for various methods of structure determination that we must pay attention to the presence of local motion.

In these simulations, chemical shift anisotropies are not included, but it was found that even if likely chemical shift tensors are included, the spectrum does not appreciably change, under the MAS frequency of ~ 5 kHz. This is fortunate, because the CSA tensors of sp^3 carbons depend heavily on circumstances, so that it is very difficult to assume them appropriately for simulations. For a directly bonded $\text{sp}^3 - \text{sp}^3$ ^{13}C spin pair, the effect of CSAs can indeed be neglected in comparison with the contribution of the dipolar coupling under MAS with a spinning speed a few times faster than $|\delta|$, according to

Figure 12 Three dimensional structure of glycylisoleucine. (a) NMR study; (b) X-ray crystallography. (Reproduced from Nomura et al.¹³ with kind permission from Kluwer Academic Publishers)

our simulations. On the other hand, for a nonbonded, namely weakly dipolar coupled sp^3-sp^3 ^{13}C spin pair, the effect of the CSAs becomes more important than for a directly bonded pair. Therefore, the CSA effect must be reduced for accurate determination of dihedral angles by using a sufficiently fast spinning speed. Then large ν_1 is needed for satisfying a DQ recoupling condition, so that selectivity is declined. Therefore, when some other sp^3 carbons exist close to the relevant carbons, the dipolar recoupling experiment (Figure 2a) does not work well, and the 2D dipolar correlation experiment (Figure 2b) is recommended.

Figure 12 shows the 3D structure constructed from the dihedral angles determined by the R2TR experiments, and that determined by X-ray crystallography. The dihedral angles determined by NMR and X-ray are $(\psi_G, \omega_G, \phi_I, \psi_I, \chi_{11}, \chi_{12}) = (180^\circ, 180^\circ, -76^\circ, 147^\circ, 178^\circ, 160^\circ)$ and $(165^\circ, 170^\circ, -70^\circ, 156^\circ, 178^\circ, 170^\circ)$, respectively. Although of course the result by NMR includes errors, we note that the structure determined by X-ray diffraction is not very accurate either. Nevertheless, both structures are in good agreement, indicating that the present approach is useful for structure determination. Further, the X-ray diffraction showed that the thermal vibration parameters of C_1^β are very large, agreeing with our observation by NMR.

5 CONCLUDING REMARKS

The complete 3D structure of a uniformly $^{13}C, ^{15}N$ -labeled Gly-Ile molecule were determined using the R2TR method. All the dihedral angles were individually determined by selectively recoupling some dipolar interactions between three or four-bonds distant spins or observing a dipolar correlation 2D powder pattern. Choosing three adjustable parameters ν_1 , ν_0 , and ν_R properly, it was possible to find a R2TR condition suitable for selective recoupling of the pair of spins concerned. Furthermore, it is not always necessary that all resonances are resolved; it is possible to monitor the recoupling-time dependence if only one of the pair of the spins concerned is resolved well from the others.

The present approach can be applied to determine the 3D structure of a small molecule and also the structure of a restricted region important to the biological function of a large system using a sample in which the region is uniformly or multiply labeled. So far quantitative structural information obtained by solid state NMR has been almost limited to a single internuclear distance or dihedral angle. The present approach increases the obtainable quantity of structural information in a single powder sample.

1 INTRODUCTION

Carbanions are ubiquitous reagents for forming carbon–carbon bonds. This review will use the fundamental questions regarding the structure and a few reactions of carbanions to illustrate the repertoire of NMR tools available to chemists. But first, a caveat. Under common solution NMR conditions, almost all carbanions are not. In solids, a counter-ion is mandatory. In solution, carbanions exist as organometallic complexes with group I cations, e.g., $(\text{CH}_3\text{Li})_4$, or their charge is delocalized onto electronegative heteroatoms commonly oxygen or nitrogen, e.g., acetylacetonate.^{1–5} NMR is the best method for characterizing their structure, and for differentiating oligomers, solvated aggregates, contact ion pairs, solvent-separated ion pairs and free ions. The comprehensive review of organolithium compounds by Günther¹ provides many well illustrated examples of lithium nmr methods for studying these compounds. The present review focuses on carbon and provides an updated supplement to Guenther's report.

2 CHEMICAL SHIFT

The ^{13}C chemical shifts of some representative organolithiums/carbanions are shown in Figure 1.^{6,7} Two scales are shown – the δ scale with $\delta = 0.0$ ppm for TMS, and the absolute shielding scale σ with $\sigma = 0$ ppm at $\delta = 185.6$ ppm.⁸ The chemical shift range of carbanions is comparable to the range for neutral organics, so charge, per se, does not dominate shifts. A practical generalization is that, when Li^+ or another alkali metal cation replaces the proton, saturated carbons are shielded with respect to their parent hydrocarbons, whereas unsaturated centers show large deshielding effects.

The degree of aggregation, the counter-ion, and its solvation, modify the shielding at the anionic carbon and beyond. The results⁹ for 3,5-di-*t*-butyl-phenyl lithium, **1**, are illustrative (Figure 2). Reich and coworkers¹⁰ have provided a benchmark study of the power of nmr to characterize organolithium solutions. They studied the monomer/dimer/tetramer equilibria of phenyl lithium as a function of solvent and temperature. The

temperature dependence of the ^{13}C and ^6Li spectra in ether is shown in Figure 3. Coupling patterns established the state of aggregation. At C_1 and C_2 , δ increases as THF coordination increases while δ decreases at C_3 and C_4 . As the changes in δ at each carbon are monotonic relative to the parent hydrocarbon, the shifts correlate with the strength of the interaction between the carbanion electron pair and its associated cation. The changes at the remote positions result from increased electron density. Similarly, on two electron reduction of aromatic hydrocarbons to form dianions, carbon is shielded by a total of ~ 135 ppm/electron.^{11,12} Actual values depend significantly on the cation.

A detailed understanding of chemical shifts requires knowledge of the principal components of the chemical shift tensor (δ_{11} , δ_{22} , δ_{33}).^{13,14} The shift observed in solution is the average of these three independent quantities. The measurement of shift tensors at individual sites is now practical through advances in solid state nmr methods,¹⁵ but few have been reported for carbanions to date.

Chemical shifts are induced by electron circulation and the major contribution for carbon comes from the paramagnetic motion of the p electrons – the Ramsey term:¹⁶

$$\sigma_{\alpha\beta}^p = \frac{\mu_0 e^2}{8\pi m^2} \sum_{\kappa} \frac{1}{E_0 - E_n} \left(\langle 0 | \sum_k \frac{\hat{t}_{k\alpha}}{r_k^3} | n \rangle \langle n | \sum_k \hat{t}_{k\beta} | 0 \rangle + \langle 0 | \sum_k \hat{t}_{k\beta} | n \rangle \langle n | \sum_k \frac{\hat{t}_{k\alpha}}{r_k^3} | 0 \rangle \right) \quad (1)$$

The induced magnetic field (paramagnetic deshielding for σ^p) is perpendicular to the preferred plane of electron circulation. The Ramsey term, which usually induces shifts to positive δ can be broken into three multiplicative factors for each electron pair and then summed over all the electrons. The terms are: $(\langle \phi_x / L_z / \phi_y \rangle \cdot \langle \phi_y^* / L_z / \phi_x^* \rangle; +C.C.)$, – the angular momentum (p character) and orbital symmetry term; $1/r^3$, the electron – nucleus radial term; and $1/(E_n - E_0)$, the electron excitation energy gap to allow circulation. Carbanion formation generates chemical shift changes from the differential motion between the carbanion electron pair and the C–H bonding pair. Within the framework of Ramsey theory, anion formation increases the effective electron–nucleus distance which reduces σ^p , while at the same time decreasing the electron energy gap which increases σ^p . The angular momentum factor will only change at second order. As the electronic factors change in opposite senses, qualitative predictions have limited utility, especially when the anion and its precursor have different geometries (e.g., propene and allyl anion). The severe problems of qualitative analysis are underlined by a consideration of the shift changes between benzene and phenyl

lithium (see below). Accurate molecular orbital calculations¹⁷ are required to predict the shifts.

2.1 Chemical Shift and Charge Density

Chemists are naturally interested in charge density probes and it is often assumed that chemical shifts – especially carbon chemical shifts are such a probe. The contrary reality is nicely illustrated by the ^{13}C chemical shift of C_1 of phenyl lithium.¹⁸ The isotropic δ value *increases* as C_1 becomes more negative (i.e., shielding *decreases* as the electron pair

becomes less well bound). Each of the three principal values of the shielding tensor for C_1 changes significantly when its formal charge diminishes from 0 in benzene to -1 in phenyl lithium (Figure 4). The largest change occurs for the in plane shielding tensor perpendicular to the carbon–lithium bond δ_{11} where $\Delta\delta$ is $+181$ ppm relative to benzene. This large paramagnetic increase in δ is induced by circulation of the lone pair about the field axis in the molecular plane and involves $n\text{--}\pi^*$ excitation. In marked contrast, δ_{33} decreases δ is -27 ppm – when the carbanion electron pair circulates about the field axis perpendicular to the molecular plane. $n\text{--}\sigma^*$ excitation now induces an increase in shielding. Thus the same pair of electrons circulating about different axes induces shifts in opposite senses relative to benzene. The third tensor value δ_{22} shows the smallest change of $+14$ ppm as the electrons which induce this shift are not involved directly in the anion creation. Two of the three principal shift tensor values have increased δ values in striking opposition to the predictions of simple shift-charge correlations.

The chemical shift of C_1 *increases* as the carbon–Li bond length *decreases* from tetramer (174.0 ppm, 2.33 Å) to dimer (188.2 ppm, 2.24 Å) to monomer (196.4 ppm, 2.14 Å).¹⁹ However, the C_1 shift in monomeric 2,4,6-tri-*t*-butylphenyl lithium in THF at -79° is 177 ppm.²⁰ Boersma and coworkers,²¹ show a comparable sequence in an exemplary study of the solid-state and solution structure of 2-methoxyphenyl lithium:– tetramer (155.9 ppm), dimer (171.1 ppm) and monomer (175.6 ppm). Different aggregation states were generated by solvent changes and confirmed by $^6\text{Li}\text{--}^{13}\text{C}$ coupling patterns. A similar trend is seen for C_1 in vinyl lithium; tetramer (183.0 ppm, 2.26 Å)²² to dimer (190.8 ppm, ?). Though the dimer structure has not yet been determined, the dimer bond lengths in α -styryl lithium are 2.36–2.42 Å²³ ($\delta_\alpha = 205.4$ ppm). A plausible explanation for the increase in δ with decrease in C–Li bond length is that there is a low lying covalent structure which has an even larger paramagnetic term than the ionic structure because of the $1/r^3$ factor. The location of the lithium ion may also be important

Figure 3 (a) ^{13}C NMR spectra of 0.08 M $\text{Ph } ^6\text{Li}$ in THF at -111°C . (b) ^{13}C NMR spectra of 0.16 M $\text{Ph } ^6\text{Li}$ in ether at -106°C . (c) Variable temperature ^{13}C and ^6Li NMR spectra of 0.08 M $\text{Ph } ^6\text{Li}$ in ether. (Reprinted with permission from Ref.¹⁰ © (1998) American Chemical Society)

as it is only in the monomer that the lithium is located in the plane of the ring. In the dimer, a pair, and in the tetramer, a trio of lithium ions is coordinated above and below the ring plane. Reich²⁴ illustrates how coordinating ligands and external agents can modify the structure and C_1 shifts in phenyl lithium (Figure 5).

Greater insight into carbanion chemical shifts requires measurement of more principal shielding values. At present, C_1 of phenyl lithium, and of lithium cyclopentadienide, are the only carbanion examples for which both experimental

tensor values and high level theoretical calculations have been reported. The principal shift tensor values²⁵ in the series lithium cyclopentadienide, (182, 114, 21 ppm), benzene, (234, 146, 9 ppm), and tropylium tetrafluoroborate (280, 168, 22 ppm) again illustrate the Ramsey electron circulation model and the importance of orbital paramagnetism for shifts. Here the number of π electrons per carbon increases and the isotropic δ values decrease linearly. However, it is still the $\pi-\sigma^*$ and $\sigma-\pi^*$ circulation where the shift changes are generated (δ_{11} major, δ_{22} minor). The shift value perpendicular

Figure 4 The simulated CP-MAS ^{13}C spectrum of 1- ^{13}C phenyl lithium based on the data of Berger et al.¹⁸ The principal values of the shift tensor are shown (values for benzene in parentheses) with the electron orbitals, and their associated electron circulations. (See also Ref.¹⁴)

to the molecular plane (δ_{33}), which is induced by π electron circulation, is almost independent of charge. Wiberg and Zilm²⁶ reached similar conclusions from calculation of the

shift differences between the methyl cation and anion – both axially symmetric. The isotropic value shifted by -480 ppm on addition of two electrons while δ_{33} only changed by 6 ppm. The calculated shift tensor, δ_{33} for methyl anion are close to the value calculated for the closed shell C^{4-} anion (-102 ppm).

The reduction of aromatic hydrocarbons to form dianions^{11,12} and more highly reduced species provides additional insight into charge induced changes in the chemical shift and Ramsey circulation. Here the changes in charge occur predominantly in the π system and ring current (magnetic susceptibility) effects are observed. The experimental results show that the change in center of gravity of the ^{13}C signals per added electron varies widely from system to system. For example, acepleiadylene ($\text{C}_{16}\text{H}_{10}$) gives $\Delta\delta/e$ of -2 ppm when reduced to the dianion but -32 ppm when reduced to the tetraanion.^{11,27} As Zanasi²⁸ and coworkers calculated, there are dramatic differences in the π circulations between neutral acepleiadylene, and its dianion – a consequence of the change in HOMO-LUMO energy gap (Figure 6). Simple charge linearity models predict enhanced shielding—just the opposite from the observed trend. By contrast, the calculated (6-31G** basis set at the HF limit) shift values closely reproduce the experimental values, and provide a corrected assignment of the quaternary carbons. Both the paramagnetic vortex in the 7 membered ring and the large increases in δ are a consequence of small energy gaps in the π system of the dianion. Here again the Ramsey circulation accounts for the shifts, even when the charge density changes are localized in the π system. All three

Figure 5 The effect of change in lithium coordination on the C_1 chemical shift of 2-methoxymethylphenyl lithium induced by coordination with pentamethyl-diethylenetriamine (PMDTA). (Spectrum kindly provided by A. W. Sanders and H. J. Reich)

Figure 6 Comparison of the ^{13}C chemical shift changes ($\Delta\delta$) induced by reduction of acepleiadylene (A) to its dianion and tetraanion and the $\Delta\delta$ calculated in Ref.²⁸ The diatropic A, (a), and paratropic A⁻², (b), π electron circulations are shown at 1 bohr above the molecular plane. (Reprinted with permission from Ref.²⁸ © (1998) American Chemical Society)

Ramsey factors are involved. Clearly, high quality theoretical calculations are required for interpretation and charge linearity models fail. Eliasson, Edlund and Muller (EEM)¹¹ provided an interesting approach to disentangling charge factors alone from the orbital symmetry/energy gap contributions to chemical shift change. They recognized that the magnitude and sense of the ring current shifts induced by the π circulation are correlated with the π energy gaps. Since proton shifts can measure the ring current, an empirical linear correlation was found between $\Delta\delta/e$ for carbon and the dia- or para-tropicity of the planar cyclic aromatic hydrocarbon. From the intercept, EEM deduced a shift of -134 ppm electron as the intrinsic charge contribution to carbon shielding for π anion formation in condensed aromatic hydrocarbons. The cyclophanes show the phenomenon and compound **2** is representative.¹² Proton shifts at each position in **2** are listed above and carbon shifts below (see **2**).

Dramatic shift differences are observed between the inside and outside protons as a consequence of the change in sense of magnetic anisotropy between $4n$ and $4n + 2$ electron systems. The carbon shifts are less sensitive because anisotropy induced shifts are independent of nucleus. Also the carbons lie in a narrow range of distances, and when the carbons constitute the equivalent current loop the anisotropic shift is zero.

Reimers, Craw and Hush (RCH)²⁹ have performed the most detailed modern analysis of the semi-empirical correlation of charge density with carbon chemical shift. They employed Tolbert and Ogle's experimental data³⁰ for α,ω -diphenyl polyenyl anions as their test set and various charge density functions obtained from AM1 calculations. RCH concluded "Atomic charges are not uniquely defined, and it is possible to arrive at quite different results depending on the particular theoretical or experimental technique used for their determination. We have shown, however, that a major cause of this nonuniqueness arises from the way in which the polarization of the chemical bonds, the bond ionicity, is treated; consequently, comparison not of the atomic charges themselves, but rather of the average charges distributed about chemical bonds leads to very similar conclusions about the charge distribution *independently* of the technique used to determine it". Their best fit was obtained with a multiparameter correlation of observed shift with average π bond charges. They found different correlations for the polyene chain carbons ($\delta_i = 132.6 + 87.8 (\pi q_i')$) and the phenyl termini ($\delta_i = 128.8 + 134.1 (\pi q_i')$). It is intriguing that the $\Delta\delta/e$ value for the polyene carbons is close to the 86.7 ppm value derived by Karplus and Pople³¹ for an electron in a $2p$ orbital based simply on the $\langle 1/r^3 \rangle_{2p}$ term and the average energy approximation. Likewise the phenyl value of $\Delta\delta/e$ is very close to the EEM value. RCH also conclude "that families of compounds similar to the ones studied herein should also show Spiesecke-Schneider correlations with different coefficients to the (non-fundamental) coefficients used herein, as is observed". They attribute these familial differences to variation in bond polarization (or bond ionicities). In other words, the Ramsey circulation varies and semi-empirical correlations must be adjusted accordingly. Once this is done, experimental anion chemical shifts can provide chemically relevant parameters such as the width of a soliton – the original goal of the studies by both Tolbert and RCH.

One more striking example of the lack of correlation between carbon chemical shift and electron density is C_{60} . The addition of 10 electrons $\delta(\text{C}^{6+}) - \delta(\text{C}^{4-})$ causes a shift of only 28.5 ppm/electron as Ramsey paramagnetic shielding is zero for these ions by symmetry and simple Lamb diamagnetism determines the shifts. The formation of the hexa-anion, C_{60}Li_6 , results in an *increase* in δ of 14 ppm.³² Buhl³³ has reproduced this value theoretically, and calculates that the next 6 electrons will induce a decrease in δ by 32 ppm in $\text{C}_{60}\text{Li}_{12}$. This is a net change of -18 ppm for the 12 electrons distributed over 60 carbons and so $\Delta\delta/e = 90$ ppm/e.

As an example of the success of theory, Buhl et al.¹⁷ applied Kutzelnigg's IGLO method to the calculation of isotropic chemical shifts in organolithium compounds. They found a very good correlation between experimental and calculated shifts for the majority of compounds shown in Figure 1. As part of this work, a linear correlation between p electron density and δ was found. However, it should be noted that in *all* compounds with $\delta > 110$ ppm, the p electron density in these *anions* was less than 1 – the exception being

the C₂ carbon of vinyl lithium where different levels of theory showed the greatest variation. Improvements in theoretical methods and more shielding tensor measurements can be expected to refine our knowledge of carbanion chemical shifts.

Despite the lack of a sound interpretive basis, chemical shift changes often provide useful guides to structures. Changes induced by solvation, degree of aggregation and temperature can be monitored and lead to meaningful structural results especially when anchored by coupling observations on limiting systems. Studies of the solvation of phenyl lithium from the relative shifts of the ring carbons provides an excellent example.¹⁰ The Schade and Boche study³⁴ of solvation of a benzyl lithium discussed under 2D methods is another.

2.2 Chemical Shift and the Structure of Equilibrating Anions

Carbon chemical shifts provide a useful guide to carbanion structure and can distinguish between localized and delocalized valence isomers. The features of the highly variegated topology of the organolithium energy surface are discerned because of the sensitivity of chemical shift to structure. Subtle distinctions with substitution, aggregation and counter-ion are found in allyl,³⁵ benzyl³⁶ and allenyl³⁷ systems. Structural issues involving benzylic anions are addressed in the coupling constant and kinetics sections. In an insightful study, Reich³⁷ has used shifts as a discriminator in many systems which might formally be written as propargyl lithiums. He established that the allenyl structure is preferred over the propargyl structure as the ¹³C shifts in the parent C₃H₃Li (C₁, 87.2; C₂, 196.4; C₃, 43.2 ppm) are clearly those of an allenic system. Figure 7 shows the resolved shifts of monomer and head-to-head dimer – also nicely illustrating ⁷Li–¹³C coupling patterns. Acetylenic valence tautomers are rare. Cyclopropyl substitution stabilizes the acetylenic tautomer and the shifts are representative (C₁, –7.5; C₂, 99.8; C₃, 68.3 ppm). The shift at the central carbon varies between the allenic (A) value, ca. 185 ppm, and the propargylic (P) value, ca. 95 ppm, as the A/P ratio changes with substituent, temperature and solvent. The A/P equilibrium constant is close to one, so minor perturbations are readily detected with this sensitive diagnostic tool. The Saunders isotopic method monitors the subtlest energy perturbations shown in the following section.

The allyl anion is a second system where different structures with similar energies may be distinguished by carbon nmr.³⁵ Limiting options include localized (L) and delocalized (D) π bonds; planar (PI) and pyramidal (Py) lithiated centers; and syn (endo) and anti (exo) stereochemistries for substituents (Figure 8). The energetics of structural equilibration may often be determined by variable temperature studies of exchange by line broadening. For example 3-neopentylallyl lithium in cyclopentane was shown to be a mixture of syn and anti forms with lithium localized at the unsubstituted terminal carbon.³⁸ Addition of coordinating ligands for lithium initiates lithium exchange between allylic carbons C₁ and C₃. Choice of substituents modulates the C₁ vs C₃ preference for anionic localization. Substituents such as Ph,³⁹ (CH₃)₃Si–,⁴⁰ and PhS–⁴¹ favor the C₁ position, while methyl prefers the C₃ position.^{35(c)} Vicinal proton–proton coupling shows that relatively small substituents, including phenyl and methyl, prefer the syn conformation.^{35(c),39} Balzer and Berger⁴² used ¹H–¹H and ¹H–⁶Li Overhauser effects to identify the endo

Figure 8 Structure of allyl anions modified from Refs.^{35,40} (see text for definitions)

and exo protons in 2-methyl-3-phenyl-allyl lithium as rotation around the C_{ipso}–C₃ bond was slow with an activation energy of 42 kJ mol^{–1}.

Fraenkel has crafted the properties of allylic⁴³ and benzylic^{36(a)} systems by substitution with the lithium coordinating ligand, –CH₂N(CH₂CH₂OCH₃)₂. In combination with a dimethylphenylsilyl substituent he stabilized the twisted propenyl lithium structure in which the Li is located in the alkene plane and a localized double bond is preferred³⁵ (Figure 8). As a consequence, the first example of ⁶Li–¹³C coupling in an allylic lithium is detected. This unique form is thought to be the transition state (presumably pyramidal) for rotation about the C₁–C₂ bond. A low barrier exchange process is found which requires carbanion inversion accompanied by rotation around the C₁–C₂ bond. The rotation around the C₂–C₃ bond was too slow to be detected at 47 °C. Fraenkel selectively placed the coordinating ligand at positions 1⁴³ or 2,³⁵ and showed how lithium location influences structural isomerism. With the substituent at the central carbon C₂, the ligand arms are diastereotopic and show resolved resonances at low temperature. Line broadening techniques were used to identify three distinct processes – inversion of the tetrahedral lithiated carbon (from 2 site exchange broadening), dissociation of the carbon lithium bond (from ⁶Li–¹³C coupling collapse), and C₁ $\rightleftharpoons$ C₃ allylic interchange (2 site exchange). With the substituent at the terminal carbon, C₁, the allylic system was induced to form both exo and endo isomers. The isomeric composition was established from 3 bond H–H coupling (endo 11.0, exo 16.2 Hz).⁴³ The activation energy for rotation around the allylic bond was determined by complex line shape fitting. Line broadening from the resolved

^{13}C signals of the diastereotopic arms of the ligand provided unique structural information about facial inversion. Measurably different barriers were found for exo–exo and endo–endo exchanges.

The structure of vinyl lithiums have been thoroughly elucidated by Bauer⁴⁴ and by Knorr.²³ The separate signals from the diastereomeric β protons in solution confirm the trigonal carbon character determined by X-ray. ^1H – ^6Li HOESY spectra identify the syn and anti protons and the substantial barrier to carbanion inversion. Inversion was studied by exchange broadening of the syn and anti protons and follows first order kinetics ($t_{1/2} \sim 3$ min at 25°C in toluene). The HOESY experiments further establish the intriguing structure of an α -lithiostyrene where the phenyl π system is overlapped with C–Li bond and is perpendicular to the carbon–carbon double bond.

2.3 Isotopic Perturbation of Chemical Shift

The Saunders isotope perturbation method⁴⁵ allows distinction between symmetrical single minimum systems and low barrier equilibrating species on a symmetric double (or higher) minimum energy surface. This is a common, but subtle, problem in carbanion chemistry where cation location is a ready source of symmetry breaking. The allyl carbanion was the first classic example studied, and Schlosser⁴⁶ showed that C_1 and C_3 were differentially shifted by 1.9 ppm when the allylic position was specifically di-deuterated in allyl magnesium bromide in THF. The deuterated carbon resonated at higher δ . In allyl lithium, an isotopic shift difference of 0.1 ppm was detected and subsequently resolved in work at higher magnetic field.⁴⁷ In monodeuterated allyl sodium and potassium, C_1 and C_3 were just resolved ($\Delta\delta \sim 0.1$ ppm) but now C_3 had the larger δ . These observations together establish that both allyl Grignard⁴⁸ and allyl lithium are a rapidly equilibrating pair of isomers while allyl sodium and potassium are delocalized. For observable distinction, the method requires that (i) the C–H bond vibrational frequencies differ in the two isomers (vinyl C–H, $>$ alkyl C–H); (ii) there be a chemical shift difference between the carbons in the two isomers (δ vinyl $>$ δ alkyl) – the larger the difference, the higher the resolving power of the method. Isotopic substitution breaks the symmetry of the energy surface, and the equilibrium shifts to favor the isomer with the deuterium on the carbon with the higher C–D vibrational frequencies. As the two isomers have different energies, the magnitude of the isotopic shift increases as the temperature is lowered. This temperature dependence is the third criterion to distinguish a delocalized single minimum structure with a large intrinsic isotope shift from an equilibrating system existing on a perturbed double minimum surface. For the single minimum cases of allyl sodium and potassium, lowering the temperature did not change the magnitude of the isotopic perturbation of chemical shifts. Schleyer⁴⁷ claimed that allyl lithium was an unsymmetrical dimer in THF. For a dimer, the isotope perturbation is the sum of contributions from head to head and head to tail forms, which should in principle, be resolvable if intra-aggregate lithium exchange can be slowed. Disubstitution at C_1 and C_3 with trimethylsilyl or phenyl substituents results in single minimum allyl lithiums.⁴⁹

Reich and Thompson³⁷ have provided a notable example of the isotope perturbation method in their study of allenyl-propargyl systems (Figure 7). Not only was the equilibrium

perturbation observed at all three unsaturated carbons, but also the minute energy differences of 0–30 cal/mol (note small calories) were measured as the position of equilibrium was perturbed by changing solvent.

The isotope perturbation method has been applied to intermolecular exchange processes. Stevenson⁵⁰ has developed an isotope enrichment method based on electron exchange equilibria between aromatic hydrocarbons and their radical anions. The isotopic perturbation of the equilibrium is monitored by the chemical shift. One other example of isotopic perturbation of chemical shift is the elegant work of Guenther employing ^6Li shifts as a probe of aggregation.⁵¹ A 50:50 mixture of protonated and perdeuterated substrates shows isotopic peak splitting with a Pascal triangle peak distribution – a monomer shows 2 equal peaks and an equilibrating tetramer a pentet.

3 COUPLING CONSTANTS

3.1 Coupling Constants, Aggregation and Solvation

Coupling to lithium is the Rosetta stone of organolithium chemistry. In early reports ^7Li – ^{13}C coupling was used to enumerate aggregation and established the dynamic character of the carbon–lithium bond.¹ Wehrli⁵² suggested that ^6Li was a superior partner because of its very small quadrupole coupling constant resulting in long relaxation times and sharp lines. Fraenkel and coworkers⁵³ quickly demonstrated its practical utility. The Guenther review¹ provides a detailed summary and many illustrative examples of the broad applicability of ^6Li –X coupling for the determination of solvation and aggregation. ^6Li has a nuclear spin of one and generates multiplets with $(2nI + 1)$ lines and intensity ratios of 1,1,1 for monomers; 1,2,3,2,1 for dimers and 1,3,6,7,6,3,1 for both trimers and the ubiquitous tetramers since only 3 of the 4 lithiums in the cube can be nearest neighbors in the absence of intra-aggregate exchange. Bond interchange processes involving inter and intra-aggregate exchange are readily distinguished as couplings are lost or averaged respectively. ^7Li –X coupling is found to be 2.641 times larger than ^6Li –X coupling – the magnetogyric ratio.

Solvation of aggregates is established via ^7Li – ^{31}P couplings in HMPA^{54,120} and ^6Li – ^{15}N coupling in amine and amide systems⁵⁵ as exchange between solvates can be slowed to less than 10 s^{-1} . Discrete ^{31}P and ^7Li signals are resolved at low temperature for individual aggregates⁵⁶ (Figure 9). The coupling patterns provide a count of neighboring nuclei in different solvates and a range of solvate levels are generated by titration. Fluorenyl lithium⁵⁴ provides a textbook example where resolved signals are observed for 0–4 coordinated HMPA and also free HMPA. Jackman⁵⁷ showed the ^6Li – ^{15}N coupling in lithium arylamides depended on aggregation (monomer 7.5 Hz, dimer 3.8 Hz). He noted that the ^6Li – ^{15}N coupling in the monomeric anilide was in the ratio of $\gamma_{\text{C}}/\gamma_{\text{Li}}$ to the ^{13}C – ^{15}N coupling in the aniline precursor but was not related to the ^1H – ^{15}N coupling.

Application of the magnitudes of coupling constants for structural interpretation has proved to be controversial. (See Ref.³⁵ and references therein). The appealing postulate¹⁹ that a large J coupling between carbon and lithium is diagnostic of a covalent bond was withdrawn by its proponents as experimental data accumulated. A recent example is the 1.4 Hz

Figure 9 ^7Li and ^{31}P NMR spectra from an HMPA titration of 0.16 M phenylthio-(3-methyl)benzyl lithium in 3:2 THF/Et₂O at -129°C . (Reprinted with permission from Ref.⁵⁶ © (1993) American Chemical Society)

^{13}C – ^6Li coupling observed to both lithiums coordinated to the tetratrimethylsilyl cyclobutadiene dianion in THF ($\delta^{13}\text{C}$ 104.1 ppm, $\delta^{6}\text{Li}$ -5.07 ppm).⁵⁸ Bonding is ionic in this planar aromatic. The theoretical basis for large J coupling across ionic systems, such as methyl lithium, has recently been provided by Bartlett and del Bene.⁵⁹ They showed that coupling was dominated by the Fermi contact mechanism (<0.1 Hz from other sources). While the calculated J increased as the bond dipole moment decreased to zero – corresponding to pure covalency – J continued to increase monotonically as the electric dipole sense was inverted.

The next interesting proposition was that ^{13}C – Li coupling was diagnostic of the state of aggregation and that carbon hybridization was a minor perturbation.¹⁹ Unfortunately, this conjecture of an approximately linear relationship between $J_{\text{C-Li}}$ and aggregation number is not supported by a broader data selection, including 7.4 Hz $J_{^{13}\text{C-}^7\text{Li}}$ for a monomeric benzyl lithium,^{36(b)} and 6.0 Hz $J_{^{13}\text{C-}^7\text{Li}}$ for a monomeric allyl lithium.^{35(b)}

Bauer and Griesinger⁴⁴ reported a complete coupling analysis for all 6 coupled nuclei in ^6Li labeled vinyl lithium which exists in dimeric and tetrameric forms in THF. A comprehensive analysis is given and small differences (1.8 Hz max.) between dimer and tetramer were detected in most couplings. The paper describes the FUCOUP method for determining the signs of active coupling constants.

The one bond carbon–hydrogen coupling has been invoked as a structural tool to infer geometry at benzylic sites.

Correlations between the benzylic ^{13}C – ^1H one bond J coupling, the benzylic carbon shift and the para proton and carbon chemical shifts generated a solvation order.³⁴ The major changes that can occur are shown in the series of PhSCHXSiPh_2 compounds⁶⁰ with values of 154 Hz ($\text{X} = \text{Li}(\text{HMPA})_4$), 135 Hz ($\text{X} = \text{H}$), to 114 Hz ($\text{X} = \text{Li}(\text{THF})$). The C–Si coupling varied in the same way, 95 Hz, 51 Hz, and 49 Hz. Change in heteroatom substituent can also induce major changes⁶¹ – $\text{PhCHLiSi}(\text{CH}_3)_3$ 119 Hz; PhCH_2Li 131 Hz; PhCHLiPh 144 Hz; and $\text{PhCHLiPO}(\text{OEt})_2$ 149.6 Hz. While the Fermi contact term has been clearly established as the major factor for coupling between first row elements,⁶² correlations with hybridization/structure must still be treated circumspectly. Stevenson's example⁶³ of J_{CH} of 145.9 Hz in cyclo-octatetraene dianion versus 158.6 Hz in benzene while the one bond J_{CC} of 55.8 Hz remains the same, is a clear challenge for theoreticians and empiricists.

The observation by Bertz⁶⁴ of ^{13}C – ^{13}C coupling (ca. 21 Hz) between ^{13}CN ligands in RCuLiCN ($\text{R} = \text{Ph}, \text{Et}, \text{Me}$) provided key proof of the coordination shell around copper.

3.2 2-D Methods

Coupling allows the generation of 2D spectra for definitive spectral assignment.

3.2.1 COSY⁶⁵

This basic form of correlation spectroscopy, and its close relative TOCSY, provides atomic connectivity information via J coupling. Early and representative examples were given by Guenther⁶⁶ who applied ^6Li – ^{13}C COSY to organolithiums soon after its development and noted the great advantage of incorporating ^6Li because of its sharp lines. In combination with a ^6Li – ^6Li COSY⁶⁷ he demonstrated the power of the technique with the solution structure of dilithium tetramethylbutatriene. A recent example is shown in Figure 10 where Collum⁶⁸ used ^6Li – ^{13}C COSY to unravel the complex catalytic mixture of chiral adducts generated from ephedrine and lithium cyclopropylacetylide.

3.2.2 HOESY⁶⁹

^1H – ^6Li HOESY (Heteronuclear Overhauser Effect Spectroscopy) is a very useful tool for establishing through-space connectivity in organolithiums. The observation of cross peaks in the two dimensional ^1H – ^6Li correlation spectra establishes spatial proximity via the ^1H – ^6Li dipole–dipole coupling constant. A cross peak shows that the lithium ion and proton of interest come, possibly transiently (see below), within 4 Å of each other on the time scale of the transfer interval (typically ~ 1 s). Schade and Boche³⁴ illustrated the utility of the technique to investigate the solvation shell of α -phenylthiobenzyl lithium in THF with added ethers and amines. They showed that one equivalent of triglyme was not sufficient to displace the THF solvation shell in the contact ion pair as cross peaks were present between lithium and protons at the benzylic and ortho positions, and the α and β THF protons, Figure 11. In a further example, Furstner et al.⁷⁰ established the perpendicular geometry of the dilithiated dianion of 1,2-diphenyl-1,2-bis(trimethylsilyl)ethane with ^1H – ^6Li

Figure 10 6Li , ${}^{13}C$ -HMQC spectrum of a sample containing 3 : 1 [6Li , ${}^{13}C$]6/[6Li]4 (0.10 M total Li titer) in 1 : 1 THF/pentane at $-125^\circ C$. The 6Li NMR spectrum is on the left axis, the ${}^6Li\{^{13}C\}$ NMR spectrum appears on the right axis, and the ${}^{13}C\{^6Li\}$ NMR spectrum is displayed on top. (Reprinted with permission from Ref.⁶⁸ © (1998) American Chemical Society)

HOESY experiments. An attempt to specifically locate the lithium cation in THF solvated 1- ${}^{13}C$ -benzyl lithium by a combination of quantitative 1H and ${}^{13}C$ NOESY measurements and relaxation time data met with moderate success.⁷¹ The HOESY study⁷² of α -lithiomethoxy-allene in d_8 -THF provides a useful cautionary example of how exchange can interfere with NOESY/HOESY experiments. The 6Li - 1H distance of short lived forms may have small contact distances and give strong HOESY peaks. In this example, the sample contained 20% butyl lithium in fast exchange with the allenyl lithium so that a single lithium peak was observed. The strongest 6Li - 1H HOESY peak was with the protons of butyl lithium although the butyl lithium peak, being the minor component in the mixture, gave the weakest peak in the direct proton spectrum.

The 7Li - 1H HOESY experiment was introduced by Bauer⁷³ who showed the experimental advantages and requirements of the pulsed field gradient method with inverse detection using butyl lithium in hexane as a test sample. The PFG version of 6Li - 1H HOESY has proved difficult to implement. Bauer⁷⁴ extended the HOESY technique to ${}^{133}Cs$ - 1H and established the composition of Lochmann's base prepared from triphenylmethyl lithium and a cesium alkoxide in THF. The HOESY cross peaks between ligand protons and lithium/cesium cations, and the 270 ppm change in Cs chemical shift on mixing, clearly showed that complete transmetalation had occurred on mixing. Bauer⁷⁵ has demonstrated that long-range ${}^{13}C$ - 6Li coupling can be used to distinguish dimers from trimers. The ${}^6Li\{^{13}C\}$ HMQC-TOCSY experiment generates 2 peaks for ${}^{13}C$ one-bond coupled to 6Li in a dimer,

Figure 11 ^1H - ^6Li HOESY spectrum of [^6Li] α -(phenylthio)-benzyl lithium with 1 mol equivalent of triglyme in 1:1 THF/ $[\text{D}_8]\text{THF}$ at 25 °C. (Reproduced by permission of Elsevier from Ref.³⁴)

and 3 peaks for the trimer where one lithium ion is 3 bonds away from the observed carbon. Bauer carefully established the precautions necessary to optimize sensitivity and avoid erroneous conclusions from peaks created in exchange processes. This experiment is related to the Gilchrist and Collum⁷⁶ method for identifying ^6Li coupled and shared between ^{15}N ligands from the multiplicity of the zero quantum line.

3.2.3 Multiple Quantum Methods

Guenther⁷⁷ has generated a remarkable set of 1D and 2D experiments to establish the unsymmetrical dimeric structure of the dilithio compound (E)-2-lithio-1-(2 lithiophenyl)-1-phenylpent-1-ene. This compound shows extensive ^6Li - ^1H and ^6Li - ^{13}C scalar couplings. Shift perturbation with D isotopic substitution was also employed. Guenther measured the ^6Li - ^6Li coupling constant of 0.16 Hz in both an INADEQUATE and a DQF-COSY experiment together with ^1H - ^6Li NOE and HOESY experiments to identify the lithiums. A detailed treatment of the INADEQUATE spectra of coupled spin 1 nuclei (e.g., ^2H , ^6Li , ^{14}N) was added subsequently.⁷⁸

3.2.4 Multiple Quantum Methods in Solids ^6Li - ^{13}C REDOR

The REDOR technique⁷⁹ has been used to measure carbon-lithium distances in lithium indenide⁸⁰ and fluorenone.⁸¹ The ^6Li - ^{13}C dipole-dipole coupling constant is 100 Hz at 3.5 Å and distances up to 4.2 Å were detected. In the TMEDA complex with lithium indenide the Li-C distances obtained from REDOR measurement were consistently larger by 0.1–0.4 Å than those obtained by X-ray. The bigger differences were at the longer distances as the accuracy of the REDOR fit diminished.

3.2.5 Lithium MQMAS and INADEQUATE

Stalke and coworkers⁸² have demonstrated the power of triple quantum magic angle spinning methods (MQMAS) to resolve different ^7Li sites in the solid microporous aggregate of methyl lithium tetramer solvated by diethoxymethane. The multiple quantum experiment revealed the 3:1 ratio of lithiums in the face and cap of the lithium tetrahedra. This information was hidden within the linewidth of the simple MAS experiment. Interestingly, the lithium experiment succeeded where the ^{13}C CPMAS spectrum failed in the resolution of the different methyl sites, identified by X-ray.

4 KINETIC PROCESSES

NMR provides a wealth of kinetic information particularly for processes with time constants in the microsecond to second range ($k = 10^6 \text{ s}^{-1}$ to 1 s^{-1}). Examples include intra- and inter-molecular exchange between aggregates; bond rotation and anion inversion; electron and proton exchange; and degenerate rearrangements that are only detectable by NMR. A practical illustration is the use of multiplet coupling patterns to distinguish between intra- and inter-aggregate exchange processes in alkyl lithiums. In their classic work on ^6Li with 1- ^{13}C propyl lithium in cyclopentane, Fraenkel and Henrichs⁵³ showed by line broadening techniques that interaggregate exchange rates were close to the same for carbon and lithium (40 s^{-1} at room temperature) and had a large negative entropy of activation. A recent version of this experiment⁸³ showed that butyl lithium forms a chiral tetramer when a chiral lithium pyrrolidide substitutes for one butyl ligand in the butyl lithium tetramer. The chiral substitution resolves the four non-equivalent Li sites into separate resonances as the temperature is lowered. The ^6Li singlet observed at room temperature resolves into 5 resonances at -81°C – from the 4 sites in the chiral tetramer plus a peak for $[\text{BuLi}]_4$. A 2D exchange spectrum (EXSY, Figure 12) lacks cross peaks between the butyl lithium peak and the other sites providing clear demonstration that intra-aggregate exchange is much faster than inter-aggregate exchange. Closer inspection shows exchange cross peaks with different intensities indicating that intra-aggregate exchange occurs by a series of two site exchange processes each with a different rate.

4.1 Carbanion Inversion

One of the best examples of the power of NMR spectroscopy to reveal the subtlety of low barrier exchange processes is found in the area of carbanion inversion and stereochemistry. The rate of inversion of carbanions is important for the selectivity of organometallic reagents. Reich's study of inversion of a substituted cyclohexyl lithium⁸⁴ is illustrative and showed half-lives of 9 min at -78° in THF. The inversion rate was accelerated by added LiBr and strongly dependent on concentration. Lithium ligation with a coordinating polyamine slowed the inversion. Other definitive examples may be found in the work from the Fraenkel,^{36(a)} Hoffman,⁸⁵ Boche,³⁴ and Reich⁸⁶ groups for heteroatom and phenyl stabilized carbanions and from the Knorr²³ group for vinyl systems. The detection of resolved peaks from diastereotopic substituents (e.g., Me_a and Me_b below) provides unambiguous

Figure 12 ^6Li – ^6Li EXSY spectrum (τ_{mix} 0.45 s) of (S)-2-(1-pyrrolidinylmethyl)pyrrolidine- $^6\text{Li}_1$ ($n\text{Bu}[^6\text{Li}]_3$) at -81.8°C in $[\text{D}_{10}]\text{DEE}$. Note absence of cross peaks between the butyl lithium peak and the other sites showing intra-aggregate exchange is faster than inter-aggregate exchange. (Reproduced by permission of Wiley-VCH from Ref.⁸³)

proof of pyramidal carbanions. Reich and Dyksta⁸⁶ showed that inversion in the mono-HMPA solvated contact ion pair ($\Delta G^\ddagger$ 32.6 kJ mol⁻¹) of $\text{Ph}(\text{Me})_2\text{Si-PhSCHLi}$ is slightly faster than the unsolvated contact ion pair in THF/ether ($\Delta G^\ddagger$ 33.5 kJ mol⁻¹). The solvent separated ion pair was found to invert more slowly than the contact pair ($\Delta G^\ddagger$ 38.1 kJ mol⁻¹). A mechanism involving Li rotation around the carbon–sulfur bond ($n\text{-}\sigma^*$ stabilizing interaction) was proposed to account for this intriguing counter-intuitive result. The solvation of the different ion pair forms was established from the coupling patterns found in the HMPA titration. In a simultaneous publication, Hoffmann and coworkers⁸⁷ confirmed the rotational character of the inversion process in a related compound by the absence of an isotope effect when the $\alpha\text{-C-H}$ was replaced with an $\alpha\text{-C-D}$. A measurable isotope effect is expected for an inversion but not for a rotation process. They also found an increased barrier with increasing steric size of the rotating group. Clearly the heteroatom is playing a key role here. In another study of inversion at a benzylic center, Peoples⁸⁸ showed that solvation by ether solvents lowered the barrier to inversion in 7-phenylnorbornyl potassium. Solvent induced dissociation of the ion pair was the rate determining step.

4.2 Carbanion Rearrangements

Skeletal rearrangements of carbanions occur much less frequently than carbocation rearrangements.⁸⁹ Ring opening of

the cyclopropylcarbinyl anion is an exception.⁹⁰ The degenerate scrambling of carbon in the bicyclo [3.2.2] nonatrienyl anion⁹¹ has been examined by Ahlberg⁹² employing specific ^{13}C and D labels. Label scrambling detected by NMR revealed this ‘hidden’ process. The lithium salt rearranged more rapidly than the potassium salt and the rearrangement was slower in the solid than DME solution. A ^{13}C – ^{13}C coupling of 62.5 Hz was reported across the allylic bond. Stevenson⁵⁰ found an unchanged ^{13}C – ^{13}C coupling of 55.8 Hz in the cyclo-octatetraene dianion-1,2-di ^{13}C after heating. This established the absence of carbon scrambling and showed that this aromatic dianion has higher thermal stability than benzene.

4.3 Kinetics of Proton Transfer

In a masterful study, Ahlberg and coworkers⁹³ measured the kinetics of proton transfer between carbanion sites in [1.1] ferrocenophanyl lithium, sodium and potassium. This is the first nmr measurement of the kinetics of reaction between a carbon acid and its conjugate base. It is better described as a proton/cation interchange as the rate determining step for the intramolecular first order rate process is strongly dependent on cation and solvent (K^+/Li^+ in THF/DEE = 4000).⁹⁴ This degenerate exchange is only detectable by NMR. The line broadening pattern is characteristic of an intramolecular proton transfer as the line broadening occurs for the 50% reaction where the spin coupled partners exchange α and β spin states (central lines) and broadening is absent for the 50% of the molecules where the spin states are conserved and α to α and β to β transfers occur (outer lines) (Figure 13). Under fast exchange conditions, the observed $J_{\text{H-H}}$ and $J_{\text{C-H}}$ splittings are half the J value for the static case and provide a diagnostic of the ‘hidden’ degenerate exchange reaction.

Klumpp and coworkers⁹⁵ have used nmr to establish the aggregation states of organolithiums in their detailed kinetic studies of the deprotonation of triphenylmethane.

4.4 Electron Exchange Processes

Rates of electron transfer processes have been extensively studied by epr methods.⁹⁶ Because of the high energetic cost of charge separation, especially in solvents with low dielectric constants, the electron transfer processes usually require coupled motion of the cation and solvent partners.⁹⁷ Rates coupled with cation and solvent. The electron/cation exchange rate for cyclo-octatetraene (COT) with its dianion is conveniently situated for nmr study by line-broadening ($t^{1/2} \sim 0.01\text{--}1\text{ s}^{-1}$) and saturation transfer kinetics ($t^{1/2} \sim 1\text{--}100\text{ s}$).⁹⁸ The transfer rate in linked di-cyclo-octatetraenes has been ‘tuned’ to the nmr regime by the activation energy for flattening the COT tub – an energetic prerequisite for electron transfer. The linker between the neutral and dianion ring modulates the activation energy of the bond shift process (carbon π systems, 55.6 kJ mol⁻¹; $\text{Si}(\text{Me})_2$, 69.5 kJ mol⁻¹). In the all carbon system with K^+ , the ET process has a 21–24 kJ mol⁻¹ higher barrier and the bond shift activation energy increases by 12 kJ mol⁻¹. In the silicon linked system the bond shift energy is almost unchanged between the neutral and dianion forms. The dianion shows an interesting cation dependent compensation of $\Delta H^\ddagger$ and $\Delta S^\ddagger$. The $\Delta H^\ddagger$ drops from 58.2 to 49.4 kJ mol⁻¹ while $\Delta S^\ddagger$ becomes more negative

Figure 13 Partial ^1H NMR spectra (499.92 MHz) of 4 mM solutions of **1** at 27.0°C showing intramolecular exchange line-broadening in different mixtures of DEE- d_{10} /THF- d_8 and the corresponding calculated spectra using DNMR5. (Reprinted with permission from Ref.^{93b} © (1997) American Chemical Society)

from -29.7 to $-56.1 \text{ J mol}^{-1} \text{ K}^{-1}$ in the series Li^+ , Na^+ , K^+ . The electron transfer process was too slow to measure by exchange line broadening for the sodium dianion with $\Delta G^\ddagger > 92 \text{ kJ mol}^{-1}$ and the lithium salt was faster than the potassium. Boman and Eliasson⁹⁹ also showed that the charged COT ring was rotating more slowly than the uncharged ring based on the ^{13}C T_1 relaxation times which differed by about a factor of two between the two rings of the salt.

Solutes with unpaired electrons may produce chemical shift changes through the hyperfine interaction in addition to shifts induced by changes in bulk magnetic susceptibility.¹⁰⁰ Separation of the two effects is achieved with the reference $\text{Cr}(\text{AcAc})_3$ which gives the bulk susceptibility correction. The hyperfine shifts induced by electron–nucleus coupling in the radical anions reveal structural, energetic, and dynamic information about weak interactions with cations and their solvation shells. For example the ^7Li shift in lithium naphthalenide solutions was found to be inversely correlated with concentration while the THF peaks shifted linearly.¹⁰¹ This revealed an ion pair exchange process with no change in the overall paramagnetism. Interpretation of the mechanism of electron–nucleus hyperfine coupling will require careful scrutiny akin to the discussion of J coupling in organolithiums.

4.5 Rapid Mixing Kinetics

McGarrity and Ogle¹⁰² introduced rapid mixing techniques to nmr in their study of THF disruption of butyl lithium aggregates. More recently, Ogle¹⁰³ has applied the methodology to butyl lithium initiated polymerization reactions of styrene.

5 MISCELLANEOUS METHODS

5.1 A Carbon-13 Carbanion Thermometer

Variable temperature studies by NMR are always plagued by the problem of determining the actual sample temperature. Differences between the instrument set/indicator temperature and actual sample temperature can be substantial and vary with sample and gas flow. Reich¹⁰⁴ has found that tris(trimethylsilyl)methane can be used as an internal thermometer for carbanion solution studies as its chemical shift is solvent and temperature dependent. Calibration curves for different solvents are required, but available from Reich.

5.2 Relaxation

Nuclear spin lattice relaxation in solution requires molecular rotation and offers another approach to study aggregation. Carbon relaxes via dipole–dipole magnetic coupling, and the alkali metals, with the exception of ^6Li , relax via quadrupole coupling. Coupling fluctuates as a function of molecular tumbling with correlation time (τ_c). Molecular tumbling times and their anisotropy are controlled by the size of the tumbling particle, solvent viscosity, and temperature.¹⁰⁵ As τ_c is proportional to the third power of the tumbling radius, dimerization can give an order of magnitude change in relaxation time. Practically, the method is limited to species with radii up to $10 \text{ \AA}$ which are in the fast motion regime for dipolar relaxation. The DOSY technique (see below) is useful above this range. Anisotropic tumbling is readily detected and may reveal

structural information.¹⁰⁶ Jackman's study¹⁰⁷ of ^{13}C relaxation in phenyllithium is a pioneering example of the information obtainable from the method. It illustrates the effects of both ^6Li – ^7Li and of ^1H – ^2D isotopic substitution on dipolar relaxation, and of applied magnetic field. At C_1 , the contribution from chemical shift anisotropy increased from 34% at 2.35 T to 90% at 8.5 T. C-4 relaxed by dipole–dipole interaction alone.

Eddlund and coworkers have studied the aggregation and ion pairing of the indenide¹⁰⁸ and fluorenone¹⁰⁹ ions by T_1 relaxation. They measured T_1 ratios between the lithium indenide and indane which ranged from 1.7 in DMF, through 2.4 in common ether solvents up to 10.9 in the poorer solvents butyl and propyl ether. These ratios were correlated with the combined molecular mass of the ion pair and its first solvation shell. The higher ratios were attributed to higher states of aggregation and included glyme-2 and glyme-3 suggestive of a solvent induced dimerization. The molecular mass correlation and T_1 averaging used here show how qualitative information can be obtained without a more accurate motional analysis.

5.3 Diffusion Studies

In principle, the size of a solvated aggregate may be determined from its diffusion coefficient and the Stokes–Einstein relationship. The DOSY technique¹¹⁰ has been applied to carbanions derived from planar aromatic hydrocarbons.¹¹¹ The anthracenide dianion and its lithium counter ions gave the same diffusion coefficient in THF and in NH_3 showing that these ions migrate together.¹¹² This is expected for measurements on the millisecond timescale of the NMR experiment and the need to maintain local charge neutrality in solution. Differential ion motion would only be observable in the presence of swamping electrolyte. The salts migrated more slowly than their parent hydrocarbons. Williard¹¹³ has used DOSY spectra to show that the dimeric aggregate of butyl lithium in THF at -84° diffuses 13% faster than its tetrameric aggregate consistent with their relative sizes.

5.4 Lithium Quadrupole Coupling Constants: (χ)

The ^7Li quadrupole coupling constant, (χ), have been measured directly in the solid state for a series of aryl lithium compounds.¹¹⁴ The results confirm Jackman's observations¹¹⁵ in solution that the coupling constant could be used to identify the degree of aggregation and the number and type of donor atoms in the coordination shell of the lithium cation. χ measures the electric field gradient at the lithium nucleus – the higher the symmetry of the coordination shell, the smaller the coupling. The largest couplings, above 400 kHz, are found for monomers. See Table 1. Guenther and coworkers¹¹⁶ have found a linear relationship between the C–Li–C angle (Φ) and the ^7Li χ for a mixed series of aryl and alkyl organolithiums whose X-ray structures were known.

$$\chi = (3.9 \pm 0.4)\Phi_{\text{CLC}} - (215.2 \pm 55.6)$$

They found a similar relationship with a similar slope for lithium amides.¹¹⁷ Solvent separated ion pairs show much smaller χ values than contact ion pairs because of the higher local symmetry of the solvation shell around the cation.

Penner¹¹⁸ has reported the solid state ^6Li spectrum of 2,4,6-tri-isopropylphenyl lithium. In addition to the quadrupole

Table 1 ^7Li Quadrupole Coupling Constants (kHz) for Lithium Salts of Organic Carbon, Nitrogen and Oxygen Acids in Ethers and Tertiary Amines

Species	C (ethers)	(ethers)	N (3° amines)	(ethers)	O (3° amines)
$\text{Li}_4\text{A}_4\text{S}_4$	85			65	40
$\text{Li}_4\text{A}_4\text{S}_n$	116, 168			105	>51
$\text{Li}_2\text{A}_2\text{S}_4$	162	155		150	120
$\text{Li}_2\text{A}_2\text{S}_2$	>250	315	306		>184
LiAS_3		210		210	167
LiAS_2		>351			

splitting of 6.6 kHz, he determined the ^6Li chemical shielding from the asymmetry of the Pake doublet. An axially symmetric shielding tensor was derived with a surprisingly large span of 24 ± 4 ppm and $\delta_{\parallel} = -15$ and $\delta_{\perp} = 9$ ppm relative to aqueous LiCl . A smaller value would be anticipated from the small chemical shift range of less than 10 ppm found in most ^6Li and ^7Li spectra in the absence of ring currents. Significant asymmetry of the electron cloud around the lithium cation would be required to produce the necessary Ramsey paramagnetism. The method cannot be used for ^7Li because of its much larger quadrupole coupling constant.

1 INTRODUCTION

Paralleling other developments in ^{13}C NMR,^{1,2} interest in ^{13}C spin relaxation data increased greatly with the availability in the early 1970s of Fourier transform methods.^{1–3} This interest initially arose for two reasons. First, it was necessary to have information about spin relaxation behavior in order to achieve sensitivity advantages approaching those theoretically possible in Fourier transform NMR experiments. Second, spin relaxation data can give chemical and dynamic molecular structural data that are either difficult or impossible to obtain from other kinds of measurements.

The ^{13}C nucleus is particularly well suited for spin relaxation studies for several reasons:

1. Since carbon atoms are usually found at the backbone of molecules, interpretation of ^{13}C relaxation behavior is generally not complicated by intermolecular relaxation processes, unlike the situation for ^1H and ^{19}F nuclei.
2. ^{13}C spectra are primarily observed under proton-decoupled conditions, where each carbon in the molecule is represented by a single spectral line whose spin–lattice (T_1) and spin–spin (T_2) relaxation times can be governed by single exponential time constants.⁴
3. The rather large chemical shift range of the ^{13}C nucleus makes it possible to resolve virtually all individual carbons, even in complex molecules. Thus, multiple sites are often available at which to probe a molecule's overall and internal motions.
4. Since ^{13}C is a rare spin (low natural abundance), consideration of ^{13}C – ^{13}C dipolar interactions or of the phenomenon of spin diffusion⁵ is usually not necessary. This greatly simplifies the interpretation of ^{13}C relaxation rates.

Carbon-13 relaxation times provide significant information in many areas of chemistry. Interpretation of ^{13}C relaxation data in terms of molecular dynamics (e.g. internal and overall molecular motions) provides the chemist with a unique and powerful probe into the detailed structure of organic molecular systems, and provides the theoretician with much needed motional data with which to test models for the microdynamic behavior of molecular systems. This potential for chemical insight, coupled with the ease of obtaining ^{13}C relaxation data

on commercially available FT NMR spectrometers, argues for a basic understanding of NMR spin relaxation parameters by most chemists. This article considers the topic of ^{13}C spin relaxation in three overall parts: (1) a description of ^{13}C spin relaxation processes, (2) a short section outlining experimental methods, and (3) discussions of several types of applications in organic chemistry.

The magnetic resonance parameters that are relevant to molecular dynamics are the nuclear spin relaxation times T_1 and T_2 and (usually) for the ^{13}C nucleus, the ^{13}C – ^1H nuclear Overhauser effect (NOE).

For a nucleus with a spin quantum number equal to $\frac{1}{2}$ (e.g., ^1H , ^{13}C , ^{19}F , ^{31}P , etc), there are two allowed orientations for each magnetic moment vector relative to an applied field, B_0 . If it is assumed that the spin system is in thermal contact with its environment and the nuclei do not strongly interact with one another, then in the absence of additional irradiation, a Boltzmann distribution of nuclei will be established among the two resultant energy states. The redistribution of populations arises from interactions of the nuclei with their surroundings. This interaction is the so-called spin–lattice relaxation process and is characterized by a relaxation time T_1 , which represents the timescale for energy transfer between the spin system and the lattice or environment. (For a liquid, the term ‘lattice’ is taken essentially as the translational, rotational, and other degrees of freedom of the molecular system.)

The resonant condition in NMR is accomplished by imposing a radiofrequency field B_1 at right angles to B_0 . When B_1 is equal to the nuclear Larmor frequency, two effects occur in the spin system. First, some nuclei in the lower energy state absorb energy from B_1 , which results in a transition to the upper energy state and a decrease in the net population difference between the states. This process decreases the value of M_z , the magnetization along the z axis coincident with B_0 . The second effect of B_1 is to generate a phase-coherent magnetization in the transverse plane, M_{xy} . After excitation, the nuclei tend to get out of phase again, thereby decreasing M_{xy} . The time constant for this process is the spin–spin relaxation time, T_2 . Loss of phase coherence arises because fluctuating local magnetic fields augment or decrease B_0 , thus causing a spread of precessional frequencies among the individual nuclei and a corresponding loss of phase coherence. A second process tending to destroy the phase coherence arises from a mutual spin flip of two nuclei, if they are initially antiparallel and have precessing magnetic fields at the proper frequency. Although this interaction conserves the energy of the spin system, it does produce an uncertainty in the energy since it limits the lifetime of a state. The magnetization M_{xy} will decay to zero as the spins resume a random precession. When $M_{xy} = 0$, the net magnetization vector lies along the z direction; thus $M = M_z$. However M_z may or may not at that moment equal M_0 . Simultaneous with the decay of M_{xy} is the restoration of M_z magnetization. The timescale for M_z to reassume the value M_0 is determined by the spin–lattice relaxation time. From the above arguments, $T_1 \geq T_2$.

Bloch viewed both of the magnetic relaxation processes as first-order decays. The usual equations for describing these decays are

$$\frac{dM_z}{dt} = \frac{-(M_z - M_0)}{T_1} \quad (1)$$

and

$$\frac{dM_{xy}}{dt} = \frac{-M_{xy}}{T_2} \quad (2)$$

These simple equations have been found to provide, in most cases, a good description of relaxation phenomena pertinent to much liquid-phase ^{13}C NMR.^{6,7} The primary concern of this article will be the spin–lattice relaxation time, T_1 , and the associated ^{13}C – ^1H NOE; in general, it is more difficult to measure ^{13}C T_2 values accurately.

Unlike most molecular relaxation processes in liquids, the timescale for the spin–lattice relaxation process is relatively long because the nuclear spin system is only weakly coupled to the other motions of the system. Experimental values of ^{13}C T_1 values are correspondingly of the order of 10^{-2} – 10^2 s and are usually in the range of 0.1 s to several seconds for typical organic compounds as neat liquids or in solution^{6,7} (provided the system is free of paramagnetic impurities). While this order of time constant indicates that the interactions governing the spin–lattice relaxation process are relatively inefficient, it is nevertheless only because of these weak interactions that nuclear spin relaxation occurs.

The coupling of the nuclear spin system to the lattice originates from the interaction of individual nuclear moments with fluctuating local magnetic fields, $\mathbf{B}_{\text{loc}}$, produced by the lattice at the nuclear site. If the various $\mathbf{B}_{\text{loc}}$ quantities have frequency components at values appropriate to the nuclear spin transition frequency, then energy can be transferred to the lattice and spin relaxation induced. The time dependence of the local fields arises from the overall and internal motions of the molecule, and other dynamic processes. To develop this link conceptually between $\mathbf{B}_{\text{loc}}$ and T_1 , it is necessary to consider the origin and some of the properties of the lattice fields.

In fluids, typical sources of $\mathbf{B}_{\text{loc}}$ are nuclear and electromagnetic dipoles, electric quadrupoles (for nuclei with spin $I > \frac{1}{2}$), anisotropy of the chemical shielding tensor, modulation of scalar coupling, and rotation of the molecule or group itself (spin rotation). The efficiency of any one of these sources in causing relaxation depends on both the amplitude of the fluctuations in $\mathbf{B}_{\text{loc}}$ and the timescale of those fluctuations. The mathematical description of the interaction of the spin with $\mathbf{B}_{\text{loc}}$ is similar for each relaxation mechanism.

Since the interaction of a ^{13}C nucleus with the magnetic field arising from an attached proton (^{13}C – ^1H nuclear dipole–nuclear dipole interaction) is most often the pathway useful in broad applications of ^{13}C spin–lattice relaxation,^{1,6,7} a brief account of the origin of the equation relating T_1 to this interaction is given immediately below.

1.1 The Dipole–Dipole Relaxation Mechanism

The prime source of ^{13}C spin relaxation in most diamagnetic liquids arises from the local magnetic fields produced by bonded or nearby protons. The instantaneous dipolar magnetic field (which may be as large as several gauss) that induces T_1 relaxation is proportional to the square of the magnetogyric ratios of both spins.

For a rigid system of intramolecular dipoles, molecular tumbling imparts the time-dependence to $\mathbf{B}_{\text{loc}}$ through the angle Θ between the through-space vector between the two

dipoles, and $\mathbf{B}_0$ (for carbons with directly bonded protons, this vector is of course coincident with the C–H bond itself). For the intermolecular case, and for intramolecular relaxation in flexible molecules, both the angle Θ and the distance between the dipoles are time-dependent, owing to relative translation as well as rotational motion. Intermolecular interactions tend to be attenuated rapidly owing to the r^{-3} dependence of $\mathbf{B}_{\text{loc}}$ for the two spins and the consequent r^{-6} dependence for T_1 relaxation of the ^{13}C nucleus. This result has important consequences for ^{13}C relaxation.

Another case of dipolar interaction is where the relaxing field has its origin with an unpaired electronic spin rather than a nuclear spin: for example, from any paramagnetic species present in the sample. Since the magnetic moment of the electron is roughly three orders of magnitude greater than nuclear moments, the fields are correspondingly more intense. When modulated by molecular tumbling, such fields can then induce very efficient nuclear spin relaxation, even at low concentration in a sample.

1.1.1 Properties and Formal Description of $\mathbf{B}_{\text{loc}}$

By assuming that the molecules constituting the liquid can be described as particles undergoing Brownian motion, the local dipolar field then has the following properties:⁸

1. $\langle \mathbf{B}_{\text{loc}}(t_0) \rangle = 0$, where $\langle \rangle$ is an average over time.
2. $\langle \mathbf{B}_{\text{loc}}^2(t) \rangle \neq 0$; i.e., the mean of the square is nonzero.
3. $\langle \mathbf{B}_{\text{loc}}(t_0) \cdot \mathbf{B}_{\text{loc}}(t + \tau) \rangle = 0$, provided that τ is sufficiently long.

At long τ , the value of $\mathbf{B}_{\text{loc}}$ at time $t + \tau$ does not in any manner depend on the value at time t . If τ is sufficiently short, then the quantity is expected to have a nonzero value.

Mathematically, these characteristics are embodied in the so-called time-dependent correlation function $G(t)$ of $\mathbf{B}_{\text{loc}}$.⁹ In a qualitative sense, such a function describes the persistence of a dynamical property of the system before being averaged out by molecular motions in the liquid, and is of particular value when two physical systems are weakly coupled, as is the case for the nuclear spin system and its lattice. The autocorrelation function of $\mathbf{B}_{\text{loc}}$ is given by the ensemble average

$$G(t) = \langle \mathbf{B}_{\text{loc}}(t_0) \cdot \mathbf{B}_{\text{loc}}(t_0 + \tau) \rangle_t \quad (3)$$

where the time-dependence is that produced by the molecular motion. The average is over an ensemble at the reference time t . Since $\langle \mathbf{B}_{\text{loc}}(t) \cdot \mathbf{B}_{\text{loc}}(t + \tau) \rangle$ is independent of the reference time, $G(t)$ is designated a correlation function of a stationary random process; $G(t)$ is independent of t_0 and is both a real and even function of τ .⁹ If the time origin is taken as $t = 0$, then

$$G(\tau) = \langle \mathbf{B}_{\text{loc}}(0) \cdot \mathbf{B}_{\text{loc}}(\tau) \rangle_0 \quad (4)$$

and $G(\tau)$ then describes the timescale for the decay of inherent motional order in the system. Information on the molecular system is dependent on the existence of $G(\tau)$, and as $G(\tau)$ decays toward zero so does knowledge of the dynamical processes at the prior time.

The Fourier transform of $G(\tau)$, the spectral density function, $J(\omega)$ provides the means of characterizing the frequency distribution and magnitude of the fluctuations in $\mathbf{B}_{\text{loc}}$; $J(\omega)$

represents a transformation from the time to the frequency domain. It is given by

$$J(\omega) = \int_{-\infty}^{+\infty} G(\tau) e^{i\omega\tau} d\tau \quad (5)$$

and represents the power available at angular frequency ω to relax the spin system. Equation (5) indicates that, if $G(\tau)$ decays slowly, information [through $J(\omega)$] will persist for a long time and the spectral lines will be narrow. If $G(\tau)$ decays rapidly, information is lost quickly and the spectral peaks will be broad.

Evaluation of equation (5) requires a description of the decay of $G(\tau)$. For a liquid, assuming exponential decay for $G(\tau)$

$$G(\tau) = \langle B_{\text{loc}}^2(0) \rangle_0 e^{-\tau/\tau_c} \quad (6)$$

where τ_c is the characteristic exponential time constant (correlation time) in which it is assumed motional order decays out of the system. It can be further assumed that the different spatial components of B_{loc} are uncorrelated, i.e., $\langle B_{\text{loc}}(x) B_{\text{loc}}(y) \rangle = 0$ but for isotropic motion they share the same correlation time, τ_c . Substitution of equation (6) into equation (5) and integration results in

$$J(\omega) = \langle B_{\text{loc}}^2(0) \rangle \frac{2\tau_c}{1 + \omega^2\tau_c^2} \quad (7)$$

From equation (7) it is evident that $J(\omega)$ is a maximum at $\omega = 0$ and is approximately constant over the range $\tau_c < \omega$; it decreases with increasing frequency as ω approaches $1/\tau_c$. The total spectral density, as a sort of probability distribution, is constant and independent of τ_c . Thus, variation in τ_c merely changes the distribution of 'spectral density' over the entire frequency spectrum.

This result indicates that T_1 goes through a minimum as a function of τ_c . Plots of T_1 versus τ_c as a function of spectrometer operating frequency are given in Figure 1. The left side of Figure 1, where T_1 is independent of spectrometer frequency, is called the region of motional narrowing. In this regime $J(\omega)$ is given by

$$J(\omega) = 2\langle B_{\text{loc}}^2(0) \rangle \tau_c \quad (8)$$

Liquids or solutions for which τ_c is within the motional narrowing limit include many organic molecules at or above room temperature. Use of increasing NMR magnetic field strengths, however, places more molecules outside the motional narrowing limit (see Figure 1). When the motional narrowing limit is valid, and when motion is isotropic, ^{13}C - ^1H dipole-dipole relaxation is described by

$$\frac{1}{T_1} = \sum_{i=1}^n \frac{\gamma_C^2 \gamma_H^2 \hbar^2}{r_{\text{CH}}^6} \tau_c \quad (9)$$

where the summation is over all nearby protons, and the r_{CH}^6 values reflect the various ^{13}C -H internuclear distances.

Figure 1 Spectral density $J(\omega)$ as a function of frequency for various values of the correlation time, τ_c (ω_0 corresponds to the nuclear Larmor frequency)

In the case of a ^{13}C nucleus that has one or more directly attached protons, longer range proton interactions can generally be ignored and equation (9) simplifies to:

$$\frac{1}{T_1} = \frac{N_H \hbar^2 \gamma_C^2 \gamma_H^2 \tau_c}{r_{\text{CH}}^6} \quad (10)$$

where N_H is the number of directly attached protons and r_{CH}^{-6} is the C-H bond length. In those cases where the molecular tumbling is anisotropic or where internal motions are present, ^{13}C dipolar relaxation (T_1 and T_2) is described by more complex equations, described elsewhere.⁸ Many applications can utilize equation (10), or approximate treatments that model motional anisotropy in terms of three orthogonal rotational diffusion constants (D_x , D_y , D_z).

1.2 Other ^{13}C Spin Relaxation Mechanisms

As described above, many carbons, particularly CH_x carbons, are relaxed completely by ^{13}C - ^1H dipole-dipole interactions. However, at increasingly high magnetic fields, and for other selected cases, a given carbon's relaxation may be dominated by other mechanisms.¹⁰ In applications of spin relaxation, it is of *paramount importance for the correct interpretation of results, that the investigator recognize all significant contributions to relaxation for the specific ^{13}C nuclei being examined.*

Briefly, the other ^{13}C spin relaxation mechanisms commonly encountered are: (a) dipolar interactions (DD) with other nuclides (e.g., ^{19}F , ^{31}P , sometimes ^{13}C , metal nuclei, etc.);

(b) dipolar interactions with unpaired electron spins (added paramagnetic agents, dissolved oxygen, etc.); (c) chemical shift anisotropy (CSA) relaxation of ^{13}C nuclei which occurs through the anisotropy of the ^{13}C shielding tensor; because CSA relaxation depends on B_0^2 as well as the square of the shielding anisotropy, it is significant, especially at higher B_0 , for sp^2 and sp carbons, and is often dominant at high B_0 for those carbons not having directly attached protons; (d) ^{13}C relaxation through scalar interactions is common for spin–spin relaxation (linewidths), but the formalism restricts scalar T_1 relaxation to carbons scalar-coupled (SC) with nuclei having a closely similar resonance frequency and/or a very large scalar coupling constant; carbons bonded to bromine atoms, for example, can have highly efficient scalar relaxation to ^{79}Br , whose resonance frequency is only 0.3% different from ^{13}C (for ^{81}Br the Δ frequency is 7.4%); and (e) spin rotation (SR) relaxation, which in very small molecules or for freely rotating groups such as the methyl group of toluene, can dominate ^{13}C relaxation. This mechanism is more common for heavy nuclides.

1.3 Relationship of T_1 to Individual Relaxation Mechanisms

In a particular compound, all or any combination of the ^{13}C relaxation mechanisms discussed above may be of potential importance. However, only a single relaxation time is measured for each carbon. This is assumed to be related to the individual mechanisms via the reciprocal relationship:

$$\frac{1}{T_1^{\text{obs}}} = \frac{1}{T_1^{\text{DD}}} + \frac{1}{T_1^{\text{SR}}} + \frac{1}{T_1^{\text{CSA}}} + \frac{1}{T_1^{\text{SC}}} + \frac{1}{T_1^{\text{other}}} \quad (11)$$

This equation ignores cross correlation between relaxation processes. Cross correlation relaxation can be important and useful.^{4b,c} It can be significant particularly between CSA and dipolar processes, but there are experimental methods for separating these effects.¹¹ Extraction of the relevant molecular information from measured T_1 values requires evaluation of the contributions from individual relaxation mechanisms.

In 1973, Levy, Cargioli, and Anet published a paper¹⁰ describing ^{13}C spin relaxation in benzene and a variety of substituted benzenoid compounds. In that early paper, evidence was found for different individual carbons having their spin relaxation controlled by each of the available spin relaxation mechanisms: dipole–dipole interactions, chemical shift anisotropy, spin rotation, and scalar interactions. It was seen that most carbons had their spin relaxation controlled by dipole–dipole interactions to attached or nearby hydrogens, except that for nonprotonated sp^2 carbons at (then) high fields (in 1973, 63 MHz operation for ^{13}C was considered high field) there were significant contributions from chemical shift anisotropy relaxation.

Another interesting exceptional case was found for the *ipso* ring carbon in bromobenzene, where the attached bromine was highly effective in producing scalar spin relaxation, at least for the ^{79}Br isotope. Because both ^{79}Br and ^{81}Br are present in roughly comparable amounts, the T_1 magnetization recovery was seen to be nonexponential (a combination of two dissimilar spin relaxation rates).¹²

In the 1973 paper on substituted benzenes,¹⁰ there was an expansion on work from Grant and others on free methyl rotation. The methyl carbon in toluene was observed to have effective spin rotation relaxation, as confirmed by variable temperature measurements. The effect of dissolved oxygen from the air was noted for these benzenoid compounds. In the case of the smaller nonpolar compounds, and for nonprotonated carbons in some of the larger substituted benzenes, oxygen from the air contributed significantly to ^{13}C overall spin relaxation. In benzene itself, dissolved oxygen resulted in a contribution of approximately 25% to the ^{13}C relaxation rate at 38 °C, while spin rotation relaxation had a comparable contribution. Observation of several phenylacetylene compounds showed that chemical shift anisotropy relaxation was a major contributor for nonprotonated sp carbons, even at modest magnetic fields.

1.3.1 ^{13}C – ^1H Dipole–Dipole Relaxation Outside of the Motional Narrowing Limit

For synthetic and biopolymers, where motion is slow and the ^{13}C – ^1H dipolar T_1 (and NOE) becomes field-dependent, it is more difficult to quantify ^{13}C – ^1H dipolar relaxation versus other contributors. However, especially for proton-bearing sp^3 carbons, it can usually be assumed that ^{13}C – ^1H dipolar relaxation is the only significant operating mechanism.

In these cases, when dipolar T_1 and observed NOE show complex behavior as a function of the NMR observed frequency (magnetic field), it is possible to model molecular dynamics in terms of the complex overall and internal motions occurring at various frequencies and, in the case of internal motions, of varying angular amplitudes. A number of models have been proposed,¹³ but many groups prefer to use a model-free description of complex dynamics initially proposed by Lipari and Szabo.¹⁴ While the model-free approach does not explain specific conformational motions, it is quite useful for the assessment of local conformational mobility in synthetic and biopolymers.^{15,16}

1.3.2 Complex Dynamics of Small Molecules; Nonexponential Decay of $G(\tau)$

In the mid-1970s it was recognized that, under a range of circumstances, the ^{13}C dipole–dipole T_1 values apparently indicative of motional narrowing in fact showed marked field-dependence.¹⁷ This occurs when there are cooperative motions, as in some samples of aggregated molecules having relatively freely moving side chains. In the first ^{13}C study of this type, the ^{13}C dipolar T_1 values for all 10 carbons in 1,2-decanediol were found to have a strong field-dependence despite being fully due to ^{13}C – ^1H dipolar interactions, and where lines were sharp and ^{13}C T_1 values were as long as 5 s (corresponding to a τ_c well within motional narrowing). The ^{13}C T_1 results of the 1,2-decanediol study¹⁷ are summarized in Table 1, along with T_1 values for 1-decanol, which can be used for comparison purposes.

The important and unexpected thing to note in Table 1 is the large difference between the 22.6 MHz and 67.9 MHz ^{13}C T_1 values of decanediol. By contrast, the ^{13}C T_1 values of 1-decanol show no field dependence, in accordance with standard theories for molecules undergoing rapid reorientation

Table 1 ^{13}C Spin–Lattice Relaxation Data for 1,2-Decanediol and 1-Decanol

Compound ^a	Temp (°C) ^b	Frequency (MHz)	^{13}C T_1 values (s) ^c									
			C-1	C-2	C-3	C-4	C-5	C-6	C-7	C-8	C-9	C-10
1,2-Decanediol	54	22.6	0.27	0.41	0.3	0.37	0.3	0.4	0.5	0.95	1.5	3.4
	54	67.9	0.5	0.7	0.5	0.6	0.6	0.7	1.0	1.8	2.7	5.3
1-Decanol	36	22.6	0.7	0.7	0.7		~1.0 ^d			1.5	2.4	3.9
	36	67.9	0.6	0.6	0.7		~1.0 ^d			1.4	2.3	3.8

^aSamples neat unless noted.^bTemperatures $\pm 1^\circ\text{C}$, measured directly before and after data collection.^cMaximum probable error $\pm 5\%$ – 10% . Decanediol and decanol data, average of two to four runs.^dPeaks insufficiently resolved for individual T_1 assignment.

in solution. These results can be interpreted in terms of a distribution of τ values for overall motion [or, equivalently, a nonexponential autocorrelation function $G(\tau)$] at the H-bond restricted end of the diol, with effective transmission of this nonideality to all the other carbons along the alkyl chain, either by the inherent intramolecular characteristics^{13b} of the chain segmented motion, or through intermolecular transmission from chain–chain entanglements.

1-Decanol is extensively hydrogen bonded in neat solution. The ^{13}C T_1 values of 1-decanol given in Table 1 do not show a significant field dependence. The two field T_1 data for decanol at 36°C thus do not require invocation of a complex cooperative motional description as in 1,2-decanediol.

The type of effect observed for the end carbons (C₇–H₁₀) of 1,2-decanediol may be observed in organized molecules, e.g., micelles, etc, and it is characteristic of complex dynamics in large biological or synthetic polymers, where relatively freely moving side groups can continue to show marked field dependence. For these cases, multiple field (frequency) ^{13}C T_1 , NOE and, where practical, T_2 measurements can provide an extremely sensitive probe of molecular dynamics, in favorable cases uniquely differentiating similar models for overall and internal dynamics.

2 MEASUREMENTS OF ^{13}C RELAXATION PARAMETERS

Pulsed Fourier transform NMR methods are available for accurately determining spin–lattice relaxation times and NOEs. In one-dimensional ^{13}C NMR, these methods have been used for over 25 years in order to determine simultaneously T_1 values for all carbons in the spectrum. Even though the measurements can be considered as routine on modern day spectrometers, there are many factors that can make the experimental values that are determined inaccurate.¹⁸ These factors include: (i) the choice of measurement pulse sequence; (ii) stability and accuracy of pulses and the spectrometer stability as a whole; (iii) data processing method used for calculation of the time constants from the experimental data; (iv) the presence of sample impurities; (v) temperature or solvent variation between experiments to be compared; (vi) sample geometry; and (vii) unusual spin relaxation characteristics, e.g., nonexponential relaxation.

Measurement of nuclear Overhauser effects similarly depends on the control of variables such as sample state and

temperature, the application of radiofrequency pulses and timing, and care in data processing. Further, both ^{13}C spin–lattice relaxation measurements and NOE experiments may become difficult for carbons having very long spin relaxation times, where the sample is limited in quantity, or where solubility is very low.

Various pulse sequences have been used to establish a nonequilibrium condition and monitor the magnetization as a function of the time variable τ , thereby measuring T_1 . Several pulse sequences directly measure NOE values, and one version of this experiment can simultaneously measure T_1 s and NOEs for all carbons (although the efficiency of this last experiment is not high). There are existing discussions of necessary precautions that should be taken in these measurements. Table 2 summarizes some of the experiments used for ^{13}C spin relaxation measurements.

Most of the experiments listed in Table 2 are straightforward; the experiments listed for the measurement of T_1 all produce a nonequilibrium magnetization with subsequent time recovery towards equilibrium being monitored by a 90° pulse. The IRFT¹⁹ and the pulse sequences most commonly used are relatively forgiving, experimentally. However, IRFT experiments can be quite lengthy when one or more carbons that are being measured have one long T_1 value. In these cases the shorter FIRFT experiment is preferred. The progressive saturation method was used in the early days of ^{13}C NMR but it is not generally used today because the technique is not as accurate in the case of mis-set pulse angles. Both progressive saturation and saturation recovery techniques utilize in most cases homospoil pulses (z homospoil) (indicated as HS in Table 2). The saturation recovery technique avoids some of the experimental problems of progressive saturation but the magnetization change measured is only half that of full inversion–recovery technique, leading to the choice of the latter in most cases. One advantage of the FIRFT pulse sequence is that for different ^{13}C nuclei in the same sample, the magnetization change being monitored can range from full inversion–recovery to essentially half of that value for very long T_1 values.

NOE measurements for ^{13}C are easily performed in most cases. Care must be taken in high dielectric samples not to heat the sample differently during relaxation pulse intervals, and in some cases authors have utilized decoupling power at a constant level but have offset the frequency sufficiently such that the protons in the sample are not affected.

Pulse sequences have been proposed to improve IRFT-type measurements²⁴ and to remove the effects of cross correlation between dipolar and chemical shift anisotropy relaxation.²⁵ Use of indirect observation (through the ^1H channel) to

measure ^{13}C T_1 and T_2 values has been demonstrated.²⁶ New variations on direct T_2 pulse schemes have been proposed that improve their accuracy.²⁷

3 OVERVIEW OF APPLICATIONS FOR ^{13}C SPIN RELAXATION MEASUREMENTS

Utilization of carbon-13 spin relaxation data for both structural and dynamic information has been widespread in the literature over the past 20 years. Molecular systems that have been examined range from one-carbon molecules to highly complex synthetic and biological macromolecules, as well as simple and complex organometallics. The theoretical underpinnings for these measurements have advanced over this time period, but the simplest theories of spin relaxation are still sufficient in many applications. This has not caused special difficulty, since cross correlation has shown the greatest effect in the simplest molecules, usually under conditions that are not pertinent to most experiments (for example, in experiments not utilizing proton decoupling). By contrast, learning the intimate details of complex molecular dynamics can require highly sophisticated treatment of relaxation data.

Use of ^{13}C spin relaxation data to obtain qualitative dynamic information is quite facile; quantitative interpretation requires more care in terms of both experiment and elucidation of the dynamics through model assumptions, even in the case of model-free approaches. For molecules that are highly associated, or that are large enough inherently to be outside the extreme spectral narrowing limit, proper interpretation of the data is best done utilizing spin relaxation data obtained across dispersed frequencies (utilizing spectrometers operating at several magnetic fields).

3.1 Structure Determination

Carbon-13 spin relaxation data can be used as primary or confirmatory evidence for the assignment of chemical structures. The inverse sixth power relationship between ^{13}C – ^1H distances and the usual observed ^{13}C dipolar T_1 values can be converted into spectral assignment information, particularly for carbons not having directly attached hydrogens and yet dipolar-relaxed from protons on adjacent or nearby carbons, or from protons in the solvent. For carbons that have one or more directly attached hydrogens, the spin relaxation data may still be useful for spectral assignments, in many cases adding an independent check on assignments made by other methods. For molecules that are globular in shape and close to isotropic in tumbling behavior, the protonated carbon T_1 values often fall into three groups: CH_2 carbons with the shortest T_1 s, CH carbons having T_1 s approximately twice that of the CH_2 carbons (the relaxation rate is half because only one hydrogen contributes to the carbon's spin relaxation), and CH_3 T_1 s ranging from 1.5-times shorter than those found for CH_2 (occasionally, for a methyl that is not rotating) to T_1 values that are longer than T_1 values observed for the CH carbons in that molecule (rapidly rotating CH_3 groups).

An early example of the use of ^{13}C T_1 values to differentiate carbons not having directly attached hydrogens, is the molecule mescaline (**1**). The three types of nonprotonated carbons on the benzene ring of mescaline have differing numbers of hydrogens in the *ortho* ring position, as shown in structure (**1**). The ^{13}C T_1 s reflect this, the longest value belonging to the carbon having no adjacent ring *ortho* hydrogens. An example showing the ^{13}C T_1 s of protonated carbons varying with the numbers of directly attached hydrogens is the molecule cholesterol (**2**). Cholesterol shows T_1 values around 0.3 s for CH_2 carbons of the steroid ring skeleton while CH ring carbons show ^{13}C T_1 values closer to 0.55 s and methyl carbons (in this case, with considerable internal mobility) have T_1 values of approximately 1 s.²⁸ In

with ^{-13}C $T_{1\rho}$ s for the four carbons being observed to be comparable to the last four carbons in the hydrogen bonded

¹³C spin-lattice relaxation measurements in conjunction with

NOE and when possible spin–spin relaxation measurements, have proven to be an important atomic probe of these internal motions. The relaxation of protonated ^{13}C nuclei is primarily dominated by the dipole–dipole interaction with the attached proton according to the following equation (valid inside or outside of the extreme narrowing limit):

$$\frac{1}{T_1} = R_1 = \frac{N_H}{20} \left(\frac{\mu_0 \gamma_C \gamma_H \hbar}{4\pi r^3} \right)^2 \times [J(\omega_C - \omega_H) + 3J(\omega_C) + 6J(\omega_C + \omega_H)] \quad (12)$$

where N_H is the number of directly bonded hydrogens, r is the average C–H bond distance, and $J(\omega)$ is the spectral density function at the three indicated frequencies.

Relaxation parameters are related to the overall and internal motions of a molecule through their dependence on the spectral density functions. For large or aggregated molecules that reorient slowly compared with the extreme narrowing limit, the description of the function for a large molecule undergoing overall isotropic motion with fast internal motion is the model-free approach by Lipari and Szabo¹⁴ in which the spectral density function is given by

$$J(\omega) = S^2 \left(\frac{\tau_c}{1 + (\omega\tau_c)^2} \right) + (1 - S^2) \left(\frac{2\tau}{1 + (\omega\tau)^2} \right) \quad (13)$$

where S^2 is a generalized order parameter describing the amplitude of the internal motion and τ_c is the overall correlation time. The quantity τ is related to the overall and effective correlation time for the internal motion by $\tau^{-1} = \tau_c^{-1} + \tau_e^{-1}$. This two-parameter fit of the relaxation data has yielded good success in describing the internal motion of certain residues in macromolecules. Clore et al.³⁴ found it necessary to expand the above equation to include the internal motions of two uncoupled processes:

$$J(\omega) = S^2 \left(\frac{\tau_c}{1 + (\omega\tau_c)^2} \right) + (1 - S_f^2) \left(\frac{2\tau_f}{1 + (\omega\tau_f)^2} \right) + (S^2 - S_f^2) \left(\frac{2\tau_s}{1 + (\omega\tau_s)^2} \right) \quad (14)$$

where ‘f’ refers to the fast motion and ‘s’ to slower motion that may not be outside the extreme narrowing limit.

The motion of large molecules can also be complicated by overall molecular shape. For globular proteins or polynucleotides of the order of 5–7 base pairs (where the length of the chain is roughly equal to the diameter), the overall motion can be described as isotropic, but with molecules in which the shape is not close to spherical the molecule itself undergoes anisotropic motion. Equation (14) can also be used to describe anisotropic motion with internal motion. In addition to this model-free formalism, a number of different equations of spectral densities have been proposed for anisotropic motion,³⁵ multiple internal rotations and restricted diffusion,³⁶ and librational motions.³⁷

Early work on the spin–lattice relaxation of carbon-13 of biological molecules provided a fragmentary analysis of internal motion. Instead of analyzing the relaxation data of a single ^{13}C resonance, usually composite ^{13}C resonances had to be studied. James³⁸ determined the internal motion

of 23 Thr residues of chymotrypsinogen to 20 ns based on the combination of spin–lattice relaxation, NOE, and off-resonance rotating frame spin–lattice relaxation techniques. These findings suggested that, on the average, the rate of motion of the Thr residues is limited, possibly by steric hindrance or by interaction of the polar hydroxy with other polar groups. Levy et al.³⁹ looked at the relaxation data for the interaction of ethidium bromide with nucleosome core length DNA, of ca. 145 bp, and determined that the overall conformational dynamics were not altered by low to moderate levels of ethidium. In addition, the flexibility of the sugar rings was reduced when ethidium intercalated in DNA. Levy et al.⁴⁰ also found that the ^{13}C relaxation parameters of double-stranded DNA molecules of 100–300 bp were well fitted by a model which assumed that DNA undergoes rapid local motions such that the C–H vectors wobble inside a conic boundary with a half angle of 20–25°. In addition to these rapid local motions, slower overall axially symmetric rotation occurs. These are a few examples of early studies of ^{13}C relaxation in which qualitative or semiquantitative dynamic information could be ascertained from a combination of different relaxation techniques.

A comprehensive interpretation of ^{13}C relaxation data had been hampered by the inherent low sensitivity of the carbon-13 nucleus, the low natural abundance of carbon-13, and the low resolution of one-dimensional spectra. These problems have been alleviated to a certain extent by the development of proton-detected two-dimensional heteronuclear relaxation experiments,⁴¹ which increase the sensitivity by approximately $(\gamma_H/\gamma_C)^{5/2}$ ⁴² and afford increased resolution by the addition of the second dimension. The pulse sequence consists of an initial DEPT sequence⁴³ to transfer the magnetization from protons to the carbon, a relaxation period T that is varied between the two-dimensional data sets, and the evolution time, followed by a second DEPT sequence in which the magnetization is transferred back from the carbon to the protons for detection. The intensities of the peaks, $I(T)$, are described by the usual T_1 equation of the inversion–recovery experiment.

Palmer et al.⁴⁴ have used this method, along with spin–spin relaxation and NOE studies, to characterize the intramolecular dynamics of Xfin-31, which is a 25-residue synthetic zinc finger peptide that is capable of binding nucleic acids and is recurrent in regulatory proteins. The studies suggest that the motion of the backbone carbons, excluding the terminal residues, are highly restricted, but with the residues forming a loop between the β -sheet and the helix showing slightly higher mobility. The motion of the side chains of the hydrophobic residues, Val and Leu, are also restricted, although they are more mobile than the backbone. These results suggest that the peptide is quite compact.

An additional development that has allowed comprehensive analysis of T_1 relaxation is site-specific ^{13}C enrichment. This has permitted certain sites in a macromolecule to be extensively studied. Nicholson et al.⁴⁵ have ^{13}C -enriched 11 leucine residues of the protein staphylococcal nuclease, which is a small enzyme of $M_r = 16800$. The leucines, which are nearly all buried within the closely packed interior, were studied with, and without, ligand binding by two-dimensional relaxation methods as described above. The parameters were fitted using the formalism of Lipari and Szabo¹⁴ [equation (14)]. The results showed a rapid rotation of the methyl group

about the $C^\gamma-C^\delta$ bond, plus a slower motion associated with the reorientation of the $C^\gamma-C^\delta$ bond axis itself. A significant increase in the order parameter, S^2 , was seen upon binding of the ligand to leucine in the vicinity of either Ca^{2+} or the pdTp heavy atoms, which indicates a localized restriction of motion in the vicinity of the ligand-binding sites.

Many groups have used relaxation data in order to characterize the motion of synthetic polymers.^{46,47} Early on, Jacob Schaefer,^{13a} using the results of carbon-13 spin-lattice relaxation times, linewidths, and NOE factors for isotactic polystyrene, *cis*-polyisoprene, and *cis*-polybutadiene, proposed a $\log \chi^2$ density function to describe the distribution of motion. The width of the distribution is a relative measure of the extent of cooperative segmental motion of the chain. In this 1973 study, it was shown that polybutadiene exhibits more long-range cooperative motions than the other two polymers studied.

3.4 Solvent Effects and Intermolecular Interactions

Unlike ^{15}N , in which intermolecular dipolar relaxation can contribute significantly to the nitrogen T_1 values carbon-13 intermolecular effects are usually negligible. Therefore, the use of ^{13}C spin-lattice relaxation to study intermolecular interactions, such as solvent effects hydrogen bonding, and ion-dipole pairing depends on the fact that the localized motions around the site of the interaction are restricted and the overall tumbling decreases due to the increased size of the complex. Both of these effects will result in a decrease in the ^{13}C spin-lattice relaxation times. These effects have been seen upon molecular association⁴⁸ and solute-solvent interactions⁴⁹ via hydrogen-bond formation.

In a study of molecular association, it was shown in 1971 by Alger, Grant, and Lyerla⁴⁸ that the carbon nuclei of formic and acetic acids have shorter T_1 s, therefore relax faster, than the corresponding methyl esters. The carboxylic acid, which is dimerized by hydrogen bonding, rotates more slowly than the methyl esters. This behavior is seen in long- and branch-chain alcohol and acids, such as decanoic acid, decanol, and 3,7-dimethyloctanol, in which the hydrophobic end shows increased mobility, i.e. longer T_1 s than the polar end which is hydrogen bonded and therefore less mobile. Other solvent effect studies had been discussed earlier.^{10,17}

The intermolecular interaction of biological molecules in solution is of biological significance. Casarotto and Craik⁵⁰ looked at the interaction of tricyclic antidepressant drugs imipramine (4) and amitriptyline (5) with sodium dodecyl sulfate (SDS) (6) micelles. The ^{13}C relaxation parameters, including T_1 and NOE measurements at two different field strengths, were fitted to the model-free formalism of Lipari

and Szabo.¹⁴ The smallest T_1 value occurs in the middle of the aliphatic chain of neat SDS with a slight increase near the headgroup and a significant increase near the terminal methyl region. This corresponds to a low value for the order parameter for the terminal methyl, which reflects increased amplitude of mobility at the end. Upon addition of the drugs, there was a significant decrease in the T_1 values with an overall increase in the S^2 values. The aromatic carbons of the drugs showed the greatest change in T_1 upon association with the micelles. This indicated a marked decrease in overall tumbling rate. The rapid internal bridge flipping of the seven-membered ring is not significantly affected in the micelles. It was concluded from the relaxation studies that there is a notable increase in the micellar volume with a reduction of motion in the SDS alkyl chains. The drugs become extended in the micelles with the tricyclic moiety occupying the hydrophobic region of the micelle and the terminal dimethylammonium ion interacting at the micelle-water interface.

4 SUMMARY

Carbon-13 relaxation data provide unique insight into the structure and, especially, the structural dynamics of organic molecular systems, including complex biomolecules. The ability of these studies to probe molecules at each atomic site, and quantitatively to reflect dynamical information, is made especially useful by the central role of carbon atoms in these molecules and by the relatively simple mechanistic relaxation pathway for most ^{13}C nuclei. Carbon-13 relaxation complements other techniques in yielding to scientists the most basic structural secrets of complex molecules.

1 INTRODUCTION AND DEFINITIONS

Whoever measures a ^{13}C NMR spectrum, detects, consciously or not, a deuterium isotope effect on the carbon chemical shift since, usually, ^{13}C spectra are recorded in deuterated solvents such as CDCl_3 . As shown in Figure 1, the deuterium causes a splitting of the carbon resonance of this solvent into three lines due to its nuclear spin $I = 1$. The center of the triplet is, however, not at the same chemical shift position as the small signal stemming from the residue of undeuterated CHCl_3 , but is displaced somewhat to lower frequency. Thus the definition of the deuterium isotope effect on the carbon chemical shift is given by equation (1), this sign convention being in accordance with the sign of the widely used substituent effects in ^{13}C NMR.

$${}^n\Delta = \delta_{\text{deuterated}} - \delta_{\text{parent}} \quad (1)$$

The superscript n in equation (1) denotes the number of chemical bonds between the deuterium atom and the carbon atom in question. Thus one might observe isotope effects over one, two, and three bonds; furthermore, long-range isotope effects over up to 12 bonds are known.¹ The numerical values of the isotope effects are usually given in ppb instead of ppm, indicating that isotope effects are typically three orders of magnitude smaller than the effect of substituents.

The large interest in this field has prompted several review articles² which have collated large amounts of data³ and provided the basis for the discussion of the theoretical⁴ and physical organic aspects^{5,6} of the effect.

2 BASIC THEORY

Isotope effects on chemical shifts are usually explained and calculated on the basis of vibrational theory. Within the Born–Oppenheimer approximation isotopes can be thought of

as being electronically equivalent, thus deuterium should have the same electronegativity, etc. as hydrogen. However, due to its higher mass, the vibrational levels for deuterium within the electronic potential are lower than those of hydrogen, as shown in Figure 2. Due to the anharmonicity of the electronic potential, on average deuterium is closer to the carbon atom. This leads to a somewhat higher electron density at carbon and, hence, to a shielding effect of the heavier isotope.

The average shielding σ of a nucleus can be expressed by equation (2)

$$\begin{aligned} \langle \sigma \rangle = & \sigma_e + \sum_i (\partial \sigma / \partial r_i)_e \langle \Delta r_i \rangle + \sum_{ij} (\partial^2 \sigma / \partial r_i \partial r_j)_e \langle \Delta r_i \Delta r_j \rangle \\ & + \sum_{ij} (\partial \sigma / \partial \alpha_{ij})_e \langle \Delta \alpha_{ij} \rangle + \dots \end{aligned} \quad (2)$$

where the subscript e denotes the equilibrium values, r_i the distances to the neighboring nuclei, and α_{ij} the bond angles involved. Isotopic substitution affects the dynamic averages $\langle \Delta r_i \rangle$, $\langle \Delta r_i \Delta r_j \rangle$, and $\langle \Delta \alpha_{ij} \rangle$. For small molecules, this model can be used for quantitative calculations. For larger and asymmetric organic molecules, a complete vibrational analysis and the calculation of the first and second derivatives are difficult to obtain.

The common quantum chemical program packages are not capable of calculating isotope effects since, due to the Born–Oppenheimer approximation, they do not distinguish between isotopes, e.g. between hydrogen and deuterium. Model MO calculations have been carried out by varying the C,H distance to simulate the shorter C,D bond.^{7,8} Although ${}^1\Delta$ values could be reproduced, the wrong sign for ${}^2\Delta$ was predicted.

2.1 ${}^1\Delta$ Isotope Effects on ^{13}C Chemical Shifts

In Table 1 some selected basic values for a series for simple compounds are given to provide an overview of the range of these ${}^1\Delta$ isotope effects.

By inspection of the few values in Table 1 several important conclusions can be drawn.

1. All ${}^1\Delta$ effects of deuterium on ^{13}C chemical shifts are negative, in accordance with vibrational theory.
2. Very good additivity is observed if more than one deuterium atom replaces hydrogen.
3. Primary, secondary, and tertiary carbon atoms in hydrocarbons show different isotope effects. There is, apparently, a dependence on the electronegativity of other substituents attached to the deuterated carbon atom. Substituents placed several bonds away can also influence the deuterium isotope effects.
4. There is a hybridization dependence and thus a bond length dependence of these isotope effects.
5. A positive charge increases, and complexation by transition metals decreases, the isotope effects.
6. A stereochemical dependence of deuterium isotope effects can be observed.

Conclusion 4 is exemplified in Figure 3. Since accurate measurements of C–H bond lengths of small organic compounds are rare, calculated values rather than experimental bond lengths were used to correlate the ${}^1\Delta$ deuterium isotope

Figure 1 125 MHz ^{13}C NMR spectrum of neat CDCl_3

Figure 2 Vibrational levels of C-H and C-D vibrations within the electronic potential of a C-H bond

effects of a large variety of aromatic heterocycles.⁹ The general outcome is that shorter bond lengths result in diminished isotope effects. Shorter bonds are believed to be less anharmonic and stronger, so that their fractional bond shortening caused by replacing hydrogen with deuterium is therefore less pronounced. Of course, such a correlation only holds in a series of closely related compounds; thus the slope of the straight line shown in Figure 3 is quite different from that obtained, for example by Günther et al., for the hydrocarbons ethane, ethene, and ethyne.¹⁰

Figure 4 shows the dependence of $^1\Delta$ isotope effects on the chemical shift in a series of *para*-substituted benzene derivatives. For such a series, it is well known that the chemical shift can be correlated with a large number of physical organic properties such as electron density, Hammett constants, or others. Apparently, the isotope effects display the same behavior as the chemical shifts, which resulted in the conclusion that deuterium isotope effects resemble all major influences on chemical shifts, simply on a very minor scale.¹¹

2.2 $^2\Delta$ Isotope Effects on ^{13}C Chemical Shifts

Some selected values of $^2\Delta$ isotope effects are given in Table 1. As can be seen immediately, there are some unexpected sign changes of the isotope effect. Whereas these values behave 'normally' in hydrocarbons and aromatic compounds, with isotope effects in the order of -100 ppb, they change their sign when a carbonyl atom¹² or a cationic center¹³ is the carbon atom in question. This led to the idea of correlating $^2\Delta$ values with the chemical shift of the corresponding carbon

Table 1 $^1\Delta$ and $^2\Delta$ Deuterium Isotope Effects on ^{13}C Chemical Shifts

Compound	$^1\Delta(\text{ppb})$	$^2\Delta(\text{ppb})$

atom.¹⁴ Since it was found that normal substituent increments over two bonds are also dependent on the chemical shift of the affected carbon atom, this behavior of isotope effects can again be viewed as a further resemblance to substituent effects. In addition, an angular dependence of $^2\Delta$ isotope effects in bicyclic carbonyl compounds was demonstrated.¹⁵

2.3 $^3\Delta$ and Long-Range Isotope Effects on ^{13}C Chemical Shifts

For a series of norbornane derivatives, it was shown that $^3\Delta$ deuterium isotope effects display a Karplus-type behavior; thus the values are dependent on the dihedral angle between the C–D bond and the corresponding C–C bond.¹⁶ CD_3 groups attached to aromatic systems exert $^3\Delta$ isotope effects which have been related to the π bond order of the corresponding C–C bond. This important result is shown in Figure 5 where both shielding and deshielding effects are observed. The correlation was interpreted in terms of hyperconjugation; compared with a CH_3 group, a CD_3 group should have a diminished hyperconjugative electron release.¹⁷

Deuterium isotope effects over more than three bonds are mainly found in extended π systems and, typically, display a sign variation along the carbon chain. Due to the many apparent similarities to substituent effects, the polar

**Figure 3** Correlation between $^1\Delta$ values and calculated $r_{\text{C-H}}$ for a series of heterocyclic aromatic compounds (taken from Nakashima et al.⁹)**Figure 4** Correlation between $^1\Delta$ values and the ^{13}C chemical shift of C-1 in 1-deutero-4-X-benzenes (taken from Berger and Diehl¹¹)

substituent constants σ_I and σ_R have been calculated by correlation analysis for deuterium itself,¹⁸ the CD_3 group, and the $\text{C}(\text{CD}_3)_3$ group.¹⁹ These values are given in Table 2.

3 DEUTERIUM ISOTOPE EFFECTS ON SPIN COUPLING CONSTANTS

The study of deuterium isotope effects on C,H spin coupling constants is far more difficult than the study of isotope effects on chemical shifts. The topic was recently critically reviewed, and it was shown that most of the older data in the literature are unreliable.²⁰ The main reason for this is that C,H spin coupling

Table 2 Polar Substituent Constants for D, CD_3 , and $\text{C}(\text{CD}_3)_3$

Group	σ_I	σ_R
D	-0.0021	-0.0003
CD_3	-0.0027	+0.0012
$\text{C}(\text{CD}_3)_3$	-0.0025	-0.0005

constants, as measured in ^{13}C NMR spectra, are usually seen as the X part of a complex spin system, which is most often of higher order. Thus, the extraction of exact C,H spin coupling constants requires careful computer simulation of high-quality spectra with excellent digital resolution. Equally good must be the measurement of the corresponding C,D spin coupling constants, where sometimes line broadening due to quadrupolar effects prohibits the evaluation in the required accuracy. From the C,D spin coupling constant, a virtual C,H spin coupling constant is calculated using the γ value of deuterium. For this calculation the best possible γ_{D} value of $6.514\,399\,178 \times 10^7 \text{ T}^{-1} \text{ s}^{-1} \text{ rad}$ should be used. The difference between the measured C,H coupling constant and this calculated value is the isotope effect. A survey of more modern, reliable data reveals that, at most, substitution of hydrogen by deuterium diminishes the C,H spin coupling constants by 0.1–0.3 Hz. There is no conclusive reason given in the literature why the shorter C–D bond length results in a diminished spin coupling constant.

4 DEUTERIUM ISOTOPE EFFECTS IN EQUILIBRATING SYSTEMS

The deuterium isotope effects discussed above can be classified as *intrinsic*, being observable in static molecules and solely dependent on their chemical structure. In addition to these *intrinsic* isotope effects there exists another class of isotope effects, which are usually significantly larger and which stem from the partition of deuterium or deuterated groups in chemical equilibria. This has been a particularly active branch of physical organic chemistry research in the last decade and was recently extensively reviewed.²¹ Although

Figure 6 Schematic diagram for the explanation of the isotopic perturbation of equilibrium (taken from Siehl²¹)

the original finding stems from Baldry and Robinson,²² the technique became most important in the field of carbocations and was named isotopic perturbation of equilibrium.²³ With this technique one can distinguish between systems which are rapidly equilibrating between two sites, and systems which have essentially a single minimum potential.

As seen from Figure 6, two rapidly equilibrating nondeuterated cations A and B would exist in equal concentrations, and C-1 and C-2 would resonate at the chemical shift position f_{aver} . Since the introduction of deuterium removes the degeneracy of the equilibrium, sites A and B are unequally populated and one observes, in addition to the *intrinsic* isotope effects, a large, temperature-dependent splitting, δ , from which the equilibrium constant can be calculated.

Another large area where deuterium takes part in chemical equilibria is the study of tautomeric systems, especially those with hydrogen bonds involved. Examples are the keto–enol equilibria of acetylacetones, enamino ketones, ketohydrazones, and similar systems.²⁴

5 CONCLUSIONS

It has been demonstrated in this article that deuterium isotope effects on chemical shifts resemble, on a minor scale, many properties of substituent effects for which a large body of data already exists. Substituent effects are, however, complicated due to the large chemical distortion they exert on a molecule. Thus the study of the small chemical shift displacements caused by deuterium, which is only a minor perturbation for the molecule, can lead to a better understanding of the chemical shift itself. Further theoretical developments are needed in order to provide predictions of these effects for medium-sized organic molecules. In systems with chemical

equilibria, the use of deuterium isotope effects has become a standard technique. As a whole, this field provides a link between physical organic chemistry and NMR spectroscopy.

1 INTRODUCTION

NMR spectroscopy is an analytical technique that provides information of both a qualitative and quantitative nature concerning purity and molecular constitution. NMR spectra can be obtained both in the liquid and solid phase, making it an ideal tool for combinatorial chemistry. This review focuses on the wealth of techniques and NMR methodologies applied to combinatorial chemistry problems. The use of NMR as library screening tool for biological activity is outside the scope of this article.¹⁻⁷

2 ANALYSIS IN SOLUTION

Much of combinatorial chemistry is performed in solution or has a solution analysis aspect to it at some stage of development. The two main directions in the area of solution phase analysis involve HPLC/NMR and Flow NMR.

3 HPLC/NMR

Performing structure elucidation of compounds in mixtures or in a high-throughput manner is a fundamental aspect of combinatorial chemistry and the coupling of HPLC with NMR represents a powerful method to aid this analysis. While this technique has received general acceptance,⁸ its routine use in combinatorial chemistry have been somewhat limited.^{9,10} Commercially available equipment generally requires micrograms of material and in its current state, HPLC/NMR is not

a high-throughput analytical tool. Specially designed probes capable of performing CE/NMR experiments on nanograms of compound have been described but as yet have not been commercialized.¹¹

4 ON-FLOW NMR

Due to the potential of combinatorial chemistry producing large numbers of individual samples, the need for automated sample changing has taken on new emphasis. Very high-throughput data collection has been solved by the mass spectrometrists and a similar system using flow allows the analysis of NMR spectra about every 2 min has been introduced by the major NMR manufacturers. It is possible to obtain NMR data on 600–700 samples or about 6 times the throughput of current robotic sample changers in a 24-h period. Optimization of the volumes of these flow cells allow for NMR spectra to be obtained for samples in the low microgram range with the ability to obtain MS and NMR data simultaneously¹² as well as the ability to perform NMR on nano-scale samples.^{11,13} Adequate solvent suppression is necessary for this tool to work effectively since most samples provided by chemists exist in protonated solvents. Fortunately, solvent suppression pulse sequences provide the solution to this troublesome experimental detail.¹⁴ A large drawback of the flow NMR technology as it currently stands involves interspersing samples in different solvents, which creates problems with resolution and carryover.

The analysis of the overabundance of NMR information that can now be collected becomes rate limiting by interpretation of the spectra, which is still a slow process. The development of expert systems and automated data interpretation and will be needed to further spur the utility of this methodology. As a result, several new processing and display options have been presented that facilitate faster, easier, and more powerful analyses of the resulting NMR data. Unfortunately, at the time of this review, the analysis of individual spectra still must be made by hand although algorithms are currently in progress to alleviate this problem. The variety of display options now becoming routine, some of which are similar to the displays used for 2D-NMR data, are changing how chemists interact with NMR data.^{15,16} Typical display characteristics of the flow NMR data are illustrated in Figures 1 and 2.

5 ANALYSIS ON SOLID PHASE

NMR is one of the most versatile tools for analysis of organic reactions and can now be used to obtain high quality spectra of compounds still attached to solid supports. Solid phase NMR analysis allows both quantitation and structure determination to be performed without the need to cleave compounds from the support and enables detection of intermediates and products unstable to cleavage conditions.

6 GEL-PHASE NMR

Early work by Manatt and coworkers¹⁷ demonstrated that gel-phase NMR could be used to study reactions on solid

Figure 1 Four different representations of the same NMR data, acquired on the 88 library members in the 2.5 mM DMSO- h_6 plate. Each plot emphasizes different aspects of the data and allows different questions to be answered. The contour plots on the top (a and b) emphasize pattern relationships, while the stacked plots on the bottom (c and d) facilitate more quantitative comparisons. The plots on the left (a and c) were ‘glued’ in groups of eight along the short axis of the titer plate, while the plots on the right (b and d) were ‘glued’ in groups of 11 along the long axis of the plate. For clarity, only the NH region at 9.7–11.1 ppm is shown here

phase. The technique of gel-phase NMR requires only a routine NMR spectrometer system since the solid support is swollen in an appropriate solvent and placed into a standard NMR tube. Nuclei such as carbon-13, phosphorus-31, or fluorine-19 can be conveniently monitored. Gel-phase ^1H NMR spectra are too broad to be used for general purposes.

^{19}F NMR is particularly useful because ^{19}F chemical shifts have a large spectral dispersion. Structural modifications quite remote from the fluorine site can give rise to useful chemical shift changes.¹⁸ High quality ^{19}F gel-phase NMR spectra can be obtained in only ten minutes on 50–200 mg of TentaGel resin. A large variety of fluorine containing building blocks

and reagents are commercially available allowing the use of fluorine as a convenient NMR reporter element for ^{19}F gel-phase NMR without requiring the synthesis of special materials. In the case of gel-phase ^{15}N NMR one must resort to isotopically labeled ^{15}N materials.¹⁹ The ^{15}N labeled amino acids are commercially available but most other compounds would require synthesis.

7 MAGIC ANGLE SPINNING (MAS) NMR

Magic angle spinning (MAS) NMR yields high quality proton and carbon NMR data on solvent swollen solid support.

Figure 2 The ^1H NMR data were obtained using automated delivery of DMSO solutions of every library member from a 96-deep well microtiter plate to a flow probe-equipped NMR spectrometer. Plate view of scoring of ^1H NMR data of library compounds. Cells shaded in gray indicate reaction mixtures which do not contain the expected resonances of the products

Broadening due to dipolar coupling, which has a strong angular dependence in the form of $(3\cos^2\theta - 1)$, where θ is the angle between the dipolar-coupled spins and the static magnetic field²⁰ can be reduced to zero by rapidly spinning the sample about an axis at 54.7° , the magic angle, relative to the static magnetic field dipolar couplings (i.e., $\cos^2\theta - 1 = 0$). Sample spinning also averages the bulk magnetic susceptibility, substantially reducing line broadening due to this factor. Therefore NMR spectra approaching the quality of that of solution-phase samples can be obtained.^{21–23} The resulting narrower line-widths also allow for increased sensitivity relative to gel-phase NMR, with the practical outcome being reduced acquisition times.

High-resolution MAS-NMR probes and the necessary hardware can readily be purchased for most high-field NMR spectrometers. Automated sample changing is available for MAS probes increasing the throughput. In general, the quality of MAS-NMR data is such that the method is amicable to a variety of two-dimensional NMR sequences. Thus making it is possible to obtain not only structural information on-resin but also conformational information as well. High-resolution MAS-NMR technology for combinatorial chemistry research is assessable for many laboratory situations. Because both quantitation and structure determination can be performed without the need to cleave compounds from the resin it is expected that MAS-NMR will take on a more significant role in the design of combinatorial chemistry libraries.

Most combinatorial chemistry has developed using resin beads as a primary format for the synthesis of non-peptide targets. Except for PEG derived solid state supports, the proton NMR spectra yield signals which are 6–10 Hz wide making it difficult to directly measure coupling constants. Since the coupling pattern and J -values are important for structure determination several strategies have been introduced to overcome this limitation²⁴ such as 2D E.COSY NMR, tilted and non-tilted two-dimensional J -resolved spectra, and 2D SECSY NMR data can also be used to obtain resolution enhanced spectra which rivals the appearance of solution NMR spectra.^{25–28}

The role of solvent in determining the linewidth and utility of 1D NMR spectra has been described.^{29,30} It has been found that the residual line broadening observed in the MAS-NMR spectra of swollen resins not averaged by MAS comes mainly from the anisotropic bulk magnetic susceptibility differences.

Figure 3 Partial 500 MHz ^1H HRMAS NMR spectra of resin-bound intermediates **5a** (A, Ellman's dihydropyran resin), **5b** (B, Wang resin), **5c** (C, NovaSyn TG resin), and **5d** (D, POEPOP resin) swollen in CDCl_3 , and partial 400 MHz ^1H NMR spectrum of compound **11** (E, solution) in CDCl_3 , showing the trimethylsilyl group chemical shift

It is most likely that this effect comes from the aromatic rings from the polystyrene resin.^{31,32} With this in mind, a new resin that does not contain the aromatic rings has been developed.³³ These PEG-based resins give higher resolution spectra than the PEG grafted resins Tenta-Gel and Argo-Gel and all polystyrene based resins. The influence on resin type can be clearly seen in the data in Figure 3.

The introduction of a gradient MAS probe has been a significant advance in the ability to obtain artifact free data. The need for gradients is in fact more pronounced for MAS-NMR data sets, since sample spinning builds into the measurement an unavoidable modulation (primarily due to RF-intensity modulation and Q-modulation) giving rise to significant t_1 -ridges.³⁴ The use of gradients allows the ability to obtain high quality HMQC and HMBC NMR spectra without the nuisance of artifactual noise stripes. The HMBC experiment is particularly important since it is one of the most powerful NMR structure determination tools.³⁵

8 PINS AND CROWNS

The crown/pin system, where resin is grafted onto a base polymer carrier, is an alternate format to resin beads, and despite usefulness of the crown/pin system for solid-phase synthesis, there have been only a few of reports utilizing MAS NMR spectroscopy to analyze crown-based reaction products. It has been demonstrated that MAS-NMR offers

the additional benefit of allowing reaction progress to be monitored sequentially on the same crown, as the crown can be returned to the reaction apparatus until the desired transformation is complete.³⁶ There are no differences in obtaining data from this convenient solid phase chemistry system verses resin and all of the experiments that work on resin beads also work for crown/pin systems.³⁷

For situations where spectral overlap exists between the compound of interest and the linker or resin, or in which the chemical transformation does not alter the number of protons, it would be expected that using MAS ¹³C-NMR would facilitate monitoring reaction progression. Unfortunately, it has been found to be necessary to entirely fill the sample rotor with shaved surface material in order to acquire interpretable carbon spectra within 12 h.³⁸

9 PEPTIDES

Peptide synthesis represents a significant area where solid phase synthesis has been applied for some time. The ability to obtain high quality spectra has played a major role in not only determining reaction products but also in understanding reaction kinetics. Step-by-step solid-phase synthesis of a ten-residue peptide was readily followed.³⁸ The full assignment of the peptide intermediates was accomplished by combined use of MAS TOCSY, MAS NOESY and MAS ¹H-¹³C HMQC data sets. Line widths in peptide studies are directly related to chain mobility, and the lack of mobility due to aggregation is a potential source of synthesis difficulties. An eight-residue peptide attached to the POEPOP 1500 resin was readily analyzed using single resin bead MAS NMR.³³ The POEPOP resin has the advantage of yielding NMR spectra that are of higher quality than polystyrene based resins. It was found that it took only 20 min data acquisition for 1.6 nmol of peptide and that two-dimensional spectra could be obtained with only 6 nmol in an overnight data acquisition.

10 DIFFUSION WEIGHTED MAS-NMR

The ability to interpret MAS ¹H NMR data can be hampered by residual solvents, other impurities, and resin linker resonances. Compounds that are not attached to the solid phase matrix are typically small molecular weight compounds and exhibit relatively fast diffusion rates. By taking advantage of differences in the apparent diffusion coefficients between the compounds attached to the resin and compounds that are free in solution the analysis of solid phase synthesis reaction using MAS-NMR can be simplified. These experiments selectively attenuate the NMR signals of fast diffusing components simplifying spectral interpretation and has been demonstrated for DMF-d₇ swollen Fmoc-isoleucine on Wang resin.^{39,40} The success of this experiment has been extended in the SPEEDY (Spin-Echo Enhanced Diffusion Filtered Spectroscopy) sequence to take advantage of the short *T*₂ relaxation times of the resin matrix.⁴¹ This sequence incorporates both PFG diffusion-weighting and a CPMG spin-echo sequence to attenuate signals with short *T*₂ relaxation times (i.e., those of the resin matrix). The combination of the PFG diffusion-weighting and spin-echo sequences selects only the NMR signals that arise from

molecules exhibiting slower self-diffusion rates and longer *T*₂ relaxation rates. Resonances in the resultant spectrum CAN then be interpreted as belonging to compounds that are attached to the resin.

11 ON-RESIN QUANTITATION

NMR spectra have even been obtained on a single bead^{42,43} and, although the practical utility of this method is still to be proven, raises the possibility of using NMR as a decoding method for combinatorial mixture screening.

One of the aspects of on resin chemistry is to be able to tell when a reaction is over and what the yield might be, without cleaving the substances from the solid phase. Often this is best accomplished using a heteronuclear nucleus such as ¹⁹F. Quantitation of on-resin chemical reactions using ¹⁹F-NMR has been exemplified. The use of a fluorinated solvent (0.2% fluorobenzene) as an internal standard for quantifying the extent of resin loading using ¹⁹F gel-phase NMR⁴⁴ has been demonstrated by comparing the ratio of the resonance intensities of the product to that of the solvent. Other reports using fluorinated linkers which are analogues of linkers commonly used in solid-phase peptide synthesis have been described. One of the linkers was used in combination with gel-phase ¹⁹F NMR spectroscopy to develop conditions for solid-phase synthesis of chemical libraries. Attachment to and cleavage from the linker could be monitored based on the chemical shift of the fluorine atom of the linker. In addition, use of the linker as internal standard allowed quantification and optimization of reactions occurring further away from the linker when fluorinated building blocks were employed. For this method, high-quality ¹⁹F NMR spectra were obtained for compounds linked to a TentaGel resin in a standard NMR tube using an ordinary NMR instrument.

A method for quantifying on-resin reaction yields using ¹⁹F-NMR, which is more amenable for MAS has also been put forward.⁴⁵ This strategy incorporates into the resin a chemically stable fluorine moiety (4-fluorostyrene) to act as an internal standard. It was found that an internal standard (4-fluorostyrene) loading of ~0.3 mmol F/g resin was sufficient to obtain a signal-to-noise ratio ≥15 using 50 mg of material in the gel-phase in a reasonable amount of spectrometer time (1 min at 470.15 MHz ¹⁹F and 6 min at 188.23 MHz ¹⁹F).

MAS ¹H-NMR can be used to quantitatively monitor solid phase reactions.⁴⁶ The kinetics of chemical reactions on solid support can be followed in situ in the NMR rotor itself. The potential applications for following synthetic chemistry on solid support are numerous and will definitely help in the acceleration of the optimization process of solid phase synthesis. The possibilities and limits of MAS NMR to detect and quantify side products during solid phase synthesis have also been evaluated. If well separated signals are available for the different molecules, reliable quantification and identification of impurities present in concentrations as low as 1% can be obtained when using a single pulse experiment on resins swollen in deuterated solvent. Using the PFG LED sequence to remove protonated solvent signals decreased sensitivity and showed differential losses of magnetization. Still, as all sample workup steps are eliminated, this technique will be helpful in detecting minority species in solid phase combinatorial chemistry, and its application at the different

steps of the reaction might lead to the early detection of otherwise unidentifiable active components.

12 MOLECULAR CONFORMATION ON-RESIN

The on-resin conformation of a reaction intermediate can have a profound effect on chemical reactivity and the success of the reaction. Because the combination of MAS and resin swelling reduce to zero the dipolar interaction but does not affect dipolar relaxation, it is possible to collect NOE data from compounds on-resin. MAS-NOE(SY) experiments can be used to obtain a conformation-based understanding of chemical reactivity and the influence of the on-resin environment on molecular conformation providing valuable information during the design phase of a combinatorial library.

The majority of effort in studying on-resin molecular conformation has been directed towards peptides, although in our laboratory the conformations of a number of organic compounds have been studied (Michael Shapiro, unpublished results). 2D MAS NOESY experiments on the peptide GPGRAF bound to TentaGel resin suggested that the peptide

adopted a biologically relevant conformation on the resin.^{47–50} The possibility of observing molecular conformations on resin could play an important future role in the design phase of combinatorial chemistry as well as helping to understand compound reactivity and the influence of the linker on both chemical reactivity and binding events. The use of new resins and modern pulse sequences aids in the ability to obtain high quality NOESY data as shown in Figure 4.

13 CONCLUSIONS

Combinatorial chemistry has rapidly moved into the drug discovery arena and is playing a major role in the pharmaceutical industry. The ability to obtain structural data and reaction course information on solid supported reactions has inspired the development of new NMR methods for combinatorial chemistry. New solution NMR methods are useful for both solid phase and solution phase combinatorial chemistry and with greatly improved throughput could be used for quality control of libraries in the future. NMR methods will continue

to be developed and will find widespread utility in combinatorial chemistry. A significant advance in the ability to obtain relatively artifact free data has been the introduction of a gradient MAS probe having the same influence for MAS NMR that it has had on liquid NMR analysis.

1 INTRODUCTION

The concept that nuclear spin–spin coupling might occur by through-space as well as through-bond interactions was introduced many years ago to account for the observations that certain atoms which are crowded against one another intramolecularly exhibit unusually large coupling constants as measured by NMR spectroscopy.^{1,2} The early work on through-space coupling was reviewed in 1975,³ and a review of various theoretical treatments of the phenomenon appeared in 1985.⁴

This article is concerned only with spin–spin coupling between pairs of magnetic nuclei in molecules that are freely tumbling in fluid solution such that direct ‘through-space’ dipole–dipole interactions between the two nuclei are averaged to zero. The observed coupling arises instead from intramolecular Fermi contact and Hund interactions involving the nuclear spins and the spins of electrons in the molecule. Fermi contact interaction between a magnetic nucleus and an electron requires these two particles to be essentially coincident in space, which is possible only if the electron is in an orbital with s character at that nucleus. The system is lower in energy if the electron and the nucleus with which it is in intimate contact have antiparallel spins. Hund interactions are operative between two electrons that are contained in two different orbitals that have some spatial overlap of their electron densities. When an electron from one of the orbitals inhabits the same region of space as an electron from the other orbital the system has a lower energy if the two electrons have parallel spins.

The phenomenon of through-space coupling has been reported for spatially proximate pairs of nuclei of various types, including ^{19}F – ^{19}F , ^1H – ^{19}F , ^{13}C – ^{19}F , ^1H – ^1H , ^{15}N – ^{19}F ,

Figure 1 Examples of through-space coupling

^{31}P – ^{19}F , and ^{13}C – ^{31}P systems. Some examples are shown in Figure 1.

Initially the proposals for the existence of a special through-space mode of coupling were greeted with some skepticism. For example, there seemed no convincing way to rule out the alternative possibility that the large coupling

constants observed for various molecules related to 1,8-difluoronaphthalene (**1**) result instead from peculiarly effective through-bond interactions in the U-shaped array of the four relevant bonds in the FCCCCF fragment. The early history of the study of the through-space coupling phenomenon was marked by attempts to dispel this skepticism. One compelling piece of evidence in this context was the report that several disubstituted 4,5-difluorophenanthrenes, in which the shortest through-bond pathway is one bond longer than that in the 1,8-difluoronaphthalene system but the intramolecular crowding between the two fluorine atoms is greater, exhibited astonishingly large coupling constants in the range 167–170 Hz;¹⁸ a value of 174 Hz was reported subsequently for the mono-substituted derivative (**2**).^{7,8} Another convincing piece of evidence was provided by a study of the analog of the enzyme dihydrofolate reductase in which the four tryptophan residues in the native enzyme had been replaced biosynthetically by 6-fluorotryptophan residues.¹⁹ It happens that the tertiary structure of this enzyme places two of these four tryptophan (or fluorotryptophan) residues, namely residues 133 and 158, in van der Waals contact with one another. The ¹⁹F NMR spectrum of a fluorine-substituted enzyme shows four fluorine signals, two singlets and two doublets with a coupling constant of 17 Hz.¹⁹ There is no reasonable way to attribute this F–F coupling to through-bond interactions, because the shortest through-bond pathway connecting the two spatially proximate fluorines is 89 bonds long!

Both through-space and through-bond interactions contribute to the observed coupling in molecules such as those shown in Figure 1. That is, the experimentally measured coupling constant J can be expressed as a sum of through-space and through-bond components, J^{TS} and J^{TB} , respectively:

$$J = J^{\text{TS}} + J^{\text{TB}} \quad (1)$$

Perhaps the central unsolved problem in the quest for a precise understanding of the dependence of through-space coupling on molecular structure is the lack of a reliable means of dissecting the observed coupling into its through-space and through-bond components. In a few atypical cases, such as the F–F coupling in the enzyme system discussed above, this dissection is easily made because it is clear that the through-bond component is zero. Although the experimentally determined values of $J(\text{FF})$ for molecules such as (**1**)–(**3**) are sufficiently large that it seems safe to conclude qualitatively that the through-space mode of coupling plays a dominant role, the actual magnitudes of the through-space components cannot be assessed quantitatively in any of these systems because there is no reliable way to determine experimentally the magnitudes of the accompanying through-bond contributions. At this time it appears that theoretical calculations offer the best, or perhaps the only, hope for evaluating the relative importance of the through-space and through-bond modes of coupling in particular molecules. Some computational methods currently under development appear promising in this context.^{4,20,21}

In the early days of the study of through-space F–F coupling a conceptual view of the mechanism of this type of coupling was put forward by one of us based on the mixing of lone-pair orbitals through overlap interactions.²² In the next section we present a modified version of this conceptual approach for various F–F systems, and then in subsequent sections we describe how this approach

can be extended to account for through-space coupling between other kinds of magnetic nuclei, as exemplified in Figure 1. It should be acknowledged at the outset that various mathematically sophisticated and computationally oriented quantum mechanical theories of through-space F–F coupling have been presented in the past by other workers.⁴ However, although quantum mechanical approaches are intrinsically superior to our conceptual approach, they have not yet proved wholly successful in giving theoretical values of F–F coupling constants that are in consistently good agreement with the experimentally observed values. Therefore we continue to think it useful to offer our orbital overlap description as a basis on which to consider the phenomenon of through-space coupling.

2 FF SYSTEMS

Through-space F–F coupling can be attributed to the overlap of a pair of nominally lone-pair orbitals, one from each of the two coupled fluorine atoms.²² The situation for the particular intramolecular orientation found in the 1,8-difluoronaphthalene system (**1**), in which the C–F bonds are coplanar and approximately parallel to one another, is illustrated by the rough diagrams given in Figure 2. The relevant basis orbitals are the two in-plane one-center atomic lone-pair orbitals $p_{\text{F}\sigma}$ and $p'_{\text{F}\sigma}$ that would be characteristic of the fluorines if they were too far apart for these two orbitals to experience overlap interactions with each other. (For simplicity we neglect here the strong mixing of these $p_{\text{F}\sigma}$ and $p'_{\text{F}\sigma}$ orbitals with σ orbitals that are part of the carbon framework of the naphthalene system.) The F–F distance in (**1**), as measured by X-ray crystallography, is 0.2584 nm.²³ This is less than twice the 0.14 nm van der Waals radius of fluorine, so in fact the $p_{\text{F}\sigma}$ and $p'_{\text{F}\sigma}$ orbitals do overlap to a small extent. As shown schematically in Figure 2, this small F–F overlap transforms the pair of one-center atomic $p_{\text{F}\sigma}$ and $p'_{\text{F}\sigma}$ orbitals into a pair of two-center molecular orbitals, a weakly bonding orbital σ_{FF} and a weakly antibonding orbital σ^*_{FF} . Although

Figure 2 Schematic representations of the approximate shapes and relative energies of the bonding and antibonding molecular orbitals, σ_{FF} and σ^*_{FF} , that result from the overlap of the in-plane lone-pair orbitals, $p_{\text{F}\sigma}$ and $p'_{\text{F}\sigma}$, on two spatially proximate fluorine atoms oriented with their C–F bonds coplanar and essentially parallel, as in 1,8-difluoronaphthalene (**1**)

this combination of one filled bonding orbital and one filled antibonding orbital leads to no net chemical bonding between the two fluorine atoms, we believe it does provide a direct four-electron linkage that allows the transmittal of nuclear spin information between the two fluorine nuclei, and thereby gives rise to through-space F–F coupling.

In this lone-pair overlap theory through-space coupling is attributed to exactly the same kinds of interactions that are involved in through-bond coupling, namely Fermi contact interactions of the spins of the two magnetic nuclei with the spins of the surrounding electrons, electron correlation in accord with the Pauli principle for the two electrons within any given orbital, and Hund interactions between the spins of electrons in different orbitals. From this perspective the only distinction between through-space and through-bond coupling is a trivial one: through-space F–F coupling is transmitted by electrons that occupy weakly bonding and weakly antibonding orbitals, whereas through-bond coupling is transmitted by electrons that occupy strongly bonding orbitals. Given this picture, the term ‘through-space coupling’ can be seen as a misnomer. Perhaps this type of coupling would be more appropriately designated ‘proximate coupling’, ‘direct coupling’, or ‘nonbonded coupling’ but it seems unlikely that chemists will readily abandon the long-used term ‘through-space coupling’ and its juxtaposition with the term ‘through-bond coupling’.

In principle, there are five different valence-level fluorine basis orbitals whose overlap interactions should be considered with regard to through-space F–F coupling: the $2s$ lone-pair orbital s_F ; the in-plane $2p$ lone-pair orbital $p_{F\sigma}$; the out-of-plane $2p$ lone-pair orbital $p_{F\pi}$; the two-center bonding orbital σ_{CF} ; and the empty two-center antibonding orbital σ^*_{CF} . The $p_{F\sigma}-p'_{F\sigma}$ interaction illustrated in Figure 2 is only one of 14 different pairwise overlap interactions whose potential role in through-space F–F coupling should be taken into account. We have chosen to begin our presentation with the 1,8-difluoronaphthalene system because of its relative simplicity; each of the other 13 overlap interactions in this system can be considered to be either nonexistent or negligibly small in magnitude for various reasons. For example, the $s_F-p'_{F\pi}$, $p_{F\sigma}-p'_{F\pi}$, $p_{F\pi}-\sigma'_{CF}$, and $p_{F\pi}-\sigma^*_{CF}$ interactions are all zero by symmetry, as illustrated by the diagrams in Figure 3, and four other overlap interactions, $s_F-\sigma'_{CF}$, $s_F-\sigma^*_{CF}$, $p_{F\sigma}-\sigma'_{CF}$,

Figure 3 Schematic representations of F–F overlap interactions in the 1,8-difluoronaphthalene system (**1**) that are forbidden by symmetry

Figure 4 Schematic representation of overlap interactions in the 1,8-difluoronaphthalene system (**1**) that are nearly forbidden by symmetry

and $p_{F\sigma}-\sigma^*_{CF}$, are nearly zero in magnitude because of local symmetry considerations as illustrated in Figure 4.

Furthermore, all of the pairwise orbital interactions other than $p_{F\sigma}-p'_{F\sigma}$ suffer from the fact that their spatial overlaps at the F–F distance of about 0.258 nm are small relative to the spatial overlap involved in the dominant $p_{F\sigma}-p'_{F\sigma}$ interaction. Finally, many of the orbital interactions are unfavorable because of a large mismatch in the energies of the interacting pairs of basis orbitals. This information is summarized in Table 1.

The σ_{FF} and σ^*_{FF} molecular orbitals shown in Figure 2 both have nodes at or very near each fluorine nucleus, so the four electrons in these two orbitals do not have significant Fermi contact with the fluorine nuclei. Instead, the Fermi contact that is relevant for the observed F–F coupling involves the electrons in the $2s$ lone-pair orbitals, s_F and s'_F . (For simplicity, the Fermi contact interactions involving the electrons in the $1s$ orbital at each fluorine nucleus are ignored here.) For a fluorine atom whose nucleus has a spin-up alignment, for example, Fermi contact interactions give rise to an enhanced probability of finding the spin-down s_F electron in the region of the s_F orbital closer to the fluorine nucleus and a correspondingly enhanced probability of finding the spin-up

Table 1 Evaluation of the Relative Magnitudes of 14 Different Types of Pairwise Orbital Overlap Interactions between the Two Fluorine Atoms in 1,8-Difluoronaphthalene (**1**)

Orbital	Orbital'	Interaction Magnitude	Explanation Regarding Magnitude (see text)
s_F	s'_F	Negligible	Long distance
	$p'_{F\sigma}$	Negligible	Long distance, energy mismatch
	$p'_{F\pi}$	Zero	Symmetry, long distance, energy mismatch
	σ'_{CF}	Negligible	Local symmetry, long distance, energy mismatch
	σ^*_{CF}	Negligible	Local symmetry, long distance, energy mismatch
$p_{F\sigma}$	$p'_{F\sigma}$	Large	Good spatial overlap, perfect energy match
	$p'_{F\pi}$	Zero	Symmetry, long distance
	σ'_{CF}	Negligible	Local symmetry, long distance
	σ^*_{CF}	Negligible	Local symmetry, long distance, energy mismatch
	$p'_{F\pi}$	Negligible	Long distance
$p_{F\pi}$	σ'_{CF}	Zero	Symmetry, long distance
	σ^*_{CF}	Zero	Symmetry, long distance, energy mismatch
	σ'_{CF}	Negligible	Long distance
σ_{CF}	σ^*_{CF}	Negligible	Long distance, energy mismatch

s_F electron in the region of the s_F orbital more remote from the fluorine nucleus. This phenomenon, in which the spin-up and spin-down electrons in a given orbital have different spatial distributions of their electron densities, is known as spin polarization. The transmission pathway for the communication of nuclear spin information between the two fluorine nuclei is completed by way of Hund interactions between the electrons in the spin-polarized s_F and s'_F orbitals and the electrons in the σ_{FF} and σ^*_{FF} orbitals. As background for our explanation about how these particular Hund interactions control through-space F–F coupling we first consider three simpler systems: an isolated fluorine atom, the hydrogen fluoride molecule, and a C–F bond.

Theoretical calculations for an isolated fluorine atom have shown that Hund interactions between the electron in the half-occupied $2p$ orbital and the electrons in the spin-polarized $2s$ orbital lead to a preference for this $2p$ electron to have its spin aligned parallel to the net electron spin density in the inner region of the $2s$ orbital (and therefore antiparallel to the spin of the nucleus) as shown in Figure 5(a).²⁴

In the hydrogen fluoride molecule electron correlation effects cause one of the two electrons in the σ_{HF} bonding orbital to be closer to the fluorine nucleus and the other σ_{HF} electron to be closer to the hydrogen nucleus at a typical instant of time. This σ_{HF} orbital closely resembles a simple $2p_F$ orbital in the spatial distribution of its electron density, and as a consequence these two orbitals have analogous Hund interactions with their spin-polarized $2s_F$ orbitals. That is, the σ_{HF} electron that is closer to the fluorine nucleus prefers to have its spin aligned parallel to the electron spin density in the inner region of the spin-polarized fluorine $2s$ orbital. The net result is that a spin-up fluorine nucleus will cause the spin-down σ_{HF} electron to be located preferentially near the fluorine end of the hydrogen fluoride molecule as illustrated in Figure 5(b). As a consequence, the spin-up σ_{HF} electron will be located preferentially near the hydrogen end of the molecule. This spin-up σ_{HF} electron can experience direct Fermi contact interactions with the hydrogen nucleus, which means that there will be an energetic advantage if the hydrogen

nucleus has a spin-down alignment as shown in Figure 5(b). This simple picture predicts that the fluorine and hydrogen nuclei will prefer to have antiparallel nuclear spins, which accounts for the fact that the one-bond $J(FH)$ coupling constant for hydrogen fluoride molecule has been found to be positive in sign by both experimental and theoretical methods.²⁵

In contrast, the one-bond $J(FC)$ coupling constant for directly bonded carbon-13 and fluorine nuclei has been found to be negative in all known cases. Because of the usual electron correlation behavior the typical instantaneous configuration within the σ_{CF} orbital will have the two electrons located near opposite ends of the C–F bond. It has been argued earlier that the σ_{CF} electron that is located closer to the fluorine end of the bond experiences greater Hund interactions with the electron spin density in the outer region of the spin-polarized fluorine $2s$ orbital.²⁶ This reversal in the Hund behavior for the electrons in the C–F bond as compared with the H–F bond was attributed to the fact that the C–F bond is longer than the H–F bond.²⁶ The net result is a preference for the spin alignments shown in Figure 5(c), with the spin-up σ_{CF} electron located near the spin-up fluorine nucleus and therefore with the spin-down σ_{CF} electron located near the carbon nucleus. This spin-down σ_{CF} electron can experience direct Fermi contact interaction with the carbon-13 nucleus, which means that there will be an energy advantage if the carbon-13 nucleus has a spin-up alignment as shown in Figure 5(c). This simple picture predicts that the carbon-13 and fluorine nuclei will prefer to have parallel nuclear spins, consistent with the experimentally observed negative signs for carbon-fluorine one-bond coupling constants.

We turn now to the σ_{FF} and σ^*_{FF} orbitals (Figure 2) that are of interest for through-space F–F coupling. As illustrated in Figure 5(d) the orbital amplitudes are such that the two electrons in the bonding σ_{FF} orbital will be located preferentially in the region between the two nuclei, whereas the two electrons in the antibonding σ^*_{FF} orbital will be located preferentially in the two outer lobes of that orbital. As a consequence of electron correlation effects, one of the electrons in each orbital will be located preferentially near one of the fluorine nuclei while the other electron in each orbital will be located preferentially near the other fluorine nucleus. We hypothesize that because of the pronounced elongation of the bonding σ_{FF} orbital [the F–F distance of about 0.258 nm in a system such as (1) is considerably longer than the typical C–F bond distance of about 0.135 nm] the two σ_{FF} electrons experience Hund interactions preferentially with the outer regions of the spin-polarized s_F and s'_F orbitals, respectively, giving rise to a preference for the electron and nuclear spin alignments shown in Figure 5(d). This spin-polarization behavior is analogous to that noted for the C–F bond in Figure 5(c). We hypothesize further that the antibonding σ^*_{FF} orbital, which lacks the elongation of the σ_{FF} orbital because of the nodal plane at the midpoint of the line joining the two fluorine nuclei, shows spin-polarization behavior analogous to that of an isolated fluorine $2p$ orbital such that the two σ^*_{FF} electrons experience Hund interactions preferentially with the inner regions of the spin-polarized s_F and s'_F orbitals, respectively. This gives rise to a preference for the electron and nuclear spin alignments shown in Figure 5(d), which is analogous to the spin-polarization behavior noted for the F and HF systems in Figure 5(a) and (b). As a consequence of the cooperative effect

Figure 5 Schematic representations of the preferred electron and nuclear spin alignments for various systems: (a) the half-occupied $2p$ orbital of an isolated fluorine atom; (b) the σ_{HF} bonding orbital of the hydrogen fluoride molecule; (c) the σ_{CF} bonding orbital of a carbon–fluorine fragment; (d) the σ^*_{FF} antibonding and σ_{FF} bonding orbitals thought to be involved in through-space F–F coupling in a molecule such as (1)

of all four electrons in the σ_{FF} and σ_{FF}^* orbitals there is an energetic advantage if the two fluorine nuclei have antiparallel spins rather than parallel spins. In this way we can account for the fact that in all of the cases in which the signs of the F–F coupling constants have been determined experimentally for molecules in which the through-space mode of F–F coupling is thought to predominate, these signs have been found to be positive.⁶ Furthermore, the theory presented here leads to the conclusion that the magnitude of the through-space component of F–F coupling should depend on the extent to which the σ_{FF} and σ_{FF}^* orbitals are differentiated from one another in their electron densities in the region near the midpoint of the line connecting the two fluorine nuclei. This differentiation should depend in turn on the extent of overlap of the $p_{F\sigma}$ and $p'_{F\sigma}$ basis orbitals (see Figure 2), and this expectation leads to three experimentally testable predictions about the magnitude of $J(FF)^{TS}$: it should fall off exponentially with the distance between the two fluorine atoms, it should depend on orientation effects as well as distance effects, and it should not depend heavily on the π -electron withdrawing or π -electron supplying effects of any substituents that are located on the carbon framework that bears the two fluorine atoms. These implications are elaborated in the following paragraphs.

Many experimental studies have indicated that through-space F–F coupling has a very steep dependence on the distance between the coupled fluorine nuclei. One such study involves 15 compounds of types (16) and (17) (Figure 6) in which various peri substituents X and Y serve to perturb the F–F distance in predictable ways.^{9,27} Systems (16) and (17) have the disadvantage that the through-bond components of the experimentally measured total F–F coupling may be large enough to muddle the interpretation of the results. But these systems have two advantages: there is no complication from out-of-plane distortions of the fluorines of the kind found, for example, in systems related to (2) and (3); and the molecules are relatively straightforward to synthesize. The experimental results for (16) and (17) are given in Table 2.

The total coupling constants $J(FF)$ were measured by ^{19}F NMR spectroscopy and the distances between the two fluorine nuclei d_{FF} were determined by averaging the results obtained by MM2 and AM1 computations. The values of $J(FF)$ cover a wide range: from 28.1 Hz for 5,6-difluoroacenaphthene,

Figure 6 The types of 1,8-difluoronaphthalene (16) and 5,6-difluoroacenaphthene (17) derivatives for which $J(FF)$ values are listed in Table 2 and plotted in Figure 7

in which the two fluorine atoms are splayed apart as a consequence of the distortions in the peri-angles caused by the strained five-membered ring, to 82.3 Hz for 4,5-dicyano-1,8-difluoronaphthalene, in which the two fluorine atoms are pushed together as a consequence of the distortions of the peri-angles in the opposite sense caused by van der Waals repulsion between the two cyano groups. A semilogarithmic plot of $J(FF)$ against d_{FF} is shown in Figure 7. The data appear to be well correlated by the straight line shown in Figure 7, which leads to the relationship:

$$J(FF) = (9.64 \times 10^5) e^{-3.78 d_{FF}} \quad (2)$$

The average vertical deviation of points from the line in Figure 7 is ± 2.6 Hz and the correlation coefficient is 0.99. [We did not include in Figure 7 the data of 5,6-difluoroacenaphthylene, which would have given a point about 9.6 Hz above the correlation line. The reason for this large discrepancy remains obscure, although we suspect that the $-\text{CH}=\text{CH}-$ bridge might give rise to an enhanced through-bond component $J(FF)^{TB}$.]

Of course in order to use these data to provide a rigorous test of the validity of the lone-pair overlap theory one would need to plot not the total coupling constant $J(FF)$, but rather the through-space component $J(FF)^{TS}$, which is given by $J(FF) - J(FF)^{TB}$ where $J(FF)^{TB}$ is the through-bond component. Unfortunately, neither the magnitude nor the sign of $J(FF)^{TB}$ is known for any of the compounds in the series, although it seems likely from the large magnitudes of the observed coupling constants that the magnitude of $J(FF)^{TB}$ is small relative to $J(FF)$. Granted that the interpretation of

Table 2 Values of the Measured F–F Coupling Constants $J(FF)$ and the Calculated F–F Distances d_{FF} for Various Molecules of Types (16) and (17), and the Amounts by which these Experimental Coupling Constants Deviate from the Linear Correlation Plotted in Figure 7 and Expressed by Equation (2)

Figure 7 Semilogarithmic plot of $J(\text{FF})$ vs. d_{FF} for the derivatives of 1,8-difluoronaphthalene and 5,6-difluoroacenaphthene listed in Table 2 and pictured in Figure 6

the plot in Figure 7 is flawed by this uncertainty about the magnitude of the through-bond contribution to the observed $J(\text{FF})$ values, it nonetheless can be argued that the linear trend in this semilogarithmic plot provides at least qualitative support for the idea that through-space F–F coupling falls off exponentially with distance.

As an aside, an indication that there is a small through-bond component in the observed coupling constants in this series can be seen from the pattern exhibited by the small deviations of the experimental $J(\text{FF})$ values from the line plotted in Figure 7. The points for all seven of the compounds with π -acceptor substituents lie above the line: dicyano, +5.8; nitro, +5.6; anhydride, +3.9; diketone, +1.8; cyano, +1.4; quinoxaline, +0.3; and dioxime, +0.1 Hz. In contrast, the points for all six of the compounds with π -donor substituents lie below the line: methyl, –0.1; bromo, –0.9; chloro, –1.3; –CH₂CH₂–, –2.2; acetamido, –3.7; and amino, –7.8 Hz. The trend in these substituent effects is similar to the trend reported for the through-bond F–F coupling that takes place through the π -electron system in the 4-substituted-1,3-difluorobenzenes.²⁸ Relative to the F–F coupling constant of +6.6 Hz for 1,3-difluorobenzene itself, π -acceptor substituents at C-4 make $J(\text{FF})$ more positive and π -donor substituents at C-4 make $J(\text{FF})$ less positive by the following increments: nitro, +5.6; cyano, +4.3; chloro, –0.4; bromo, –0.5; methyl, –2.0; and amino, –8.7 Hz. It is perhaps not unreasonable to suspect that the 4-substituted-1,3-difluorobenzenes and the 4-substituted-1,8-difluoronaphthalenes may be analogous with respect to through-bond coupling through the π system because these two families of molecules share some common structural features; in each family the two fluorines are unconjugated with each other and separated by four bonds, and the substituent is *para* with respect to one of the fluorine atoms and also conjugated with the other fluorine atom.

Figure 8 Schematic representations of several types of orbital overlap that may play a role in through-space F–F coupling in 4,5-difluorophenanthrene systems such as (2)

For 4,5-difluorophenanthrenes such as (2), the C–F bonds are neither parallel nor coplanar, which makes the orbital overlap picture of through-space F–F coupling more complicated than that described above for the 1,8-difluoronaphthalenes such as (1). As illustrated in Figure 8, the orientation of the two fluorine atoms in the 4,5-difluorophenanthrene system may allow contributions to through-space F–F coupling from overlap interactions of the $p_{\text{FF}}-\sigma'_{\text{CF}}$, $p_{\text{FF}}-\sigma^{*'}_{\text{CF}}$, and $p_{\text{FF}}-p'_{\text{F}\pi}$ types in addition to the major contribution arising from overlap interaction of the $p_{\text{FF}}-p'_{\text{FF}}$ type. These additional modes of overlap may be responsible for the fact that the measured value of 174 Hz for the F–F coupling constant for 4,5-difluoro-1-methylphenanthrene (2) is so much larger than the value of 97 Hz that would have been predicted from the correlation line in Figure 7 for the F–F distance of 0.2434 nm found experimentally for (2).²⁹ One should be cautious, however, about attempting quantitative comparisons involving $J(\text{FF})$ values in different systems such as 1,8-difluoronaphthalenes and 4,5-difluorophenanthrenes because of the uncertainties about the magnitudes and the signs of the through-bond components.

Yet another spatial array that leads to through-space F–F coupling is found in 1,12-difluorobenzo[*c*]phenanthrenes such as (3). For steric reasons this ring system adopts a helical structure such that the dominant orbital overlap interaction leading to through-space coupling between the two fluorine atoms involves the ‘out-of-plane’ $p_{\text{F}\pi}$ and $p'_{\text{F}\pi}$ lone-pair orbitals as illustrated in Figure 9. (For simplicity in this conceptual presentation we have neglected the strong mixing of these $p_{\text{F}\pi}$ and $p'_{\text{F}\pi}$ orbitals with various π orbitals that are characteristic of the benzo[*c*]phenanthrene ring system.) For the particular example of 4-bromo-1,12-difluorobenzo[*c*]phenanthrene the F–F distance is 0.2535 nm and the value of $J(\text{FF})$ is 45 Hz.^{8,29} At this F–F distance the correlation line for the 1,8-difluoronaphthalene system in Figure 7 would predict a significantly larger value of 66 Hz for $J(\text{FF})$. This discrepancy may reflect an orientation effect: the $p_{\text{FF}}-p'_{\text{FF}}$ overlap in the 1,8-difluoronaphthalene system is nearly optimum because the orbital axes are almost colinear, whereas the $p_{\text{F}\pi}-p'_{\text{F}\pi}$ overlap in the 1,12-difluorobenzo[*c*]phenanthrene system is less than optimum because of the significant departure of the orbital axes from colinearity, as shown in Figure 9. Once again, however, such comparisons between two different systems are risky because of our lack of knowledge of the through-bond contributions to the observed values of $J(\text{FF})$.

3 NF AND PF SYSTEMS

The lone-pair overlap theory presented here can be extended in a simple way to account for two other types of through-space coupling between spatially proximate atoms bearing lone

Figure 9 Schematic representations from two vantage points of the bonding and antibonding orbitals, σ_{FF} and σ_{FF}^* , resulting from the mutual overlap of the two 'out-of-plane' lone-pair orbitals, $p_{F\pi}$ and $p'_{F\pi}$, in 1,12-difluorobenzo[c]phenanthrene systems such as (3)

Figure 10 Schematic representations of the approximate shapes and relative energies of the bonding and antibonding molecular orbitals, σ_{NF} and σ_{NF}^* , that result from the overlap of an in-plane p_F lone-pair orbital and an sp^2_N lone-pair orbital on spatially proximate fluorine and nitrogen atoms oriented as in oxime acetate (12)

pairs, namely N–F and P–F coupling. The lone-pair orbital overlap interactions thought to be important for through-space N–F coupling are illustrated in Figure 10 for a structural array similar to that in oxime acetate (12). Through-space P–F coupling in molecules such as (14) can be accounted for in an analogous fashion. The dependence of N–F and P–F through-space coupling on distance and orientation effects appears to be similar to the dependence on these two factors found for the much more thoroughly studied through-space coupling in F–F systems.^{9,14,30}

4 HF, CF, AND CP SYSTEMS

The lone-pair overlap theory can be extended yet further by hypothesizing that through-space coupling can result from

lone-pair–bond-pair overlap as well as from lone-pair–lone-pair overlap as considered above. Through-space H–F and C–F coupling has been extensively documented in a variety of molecules in which either the hydrogen end or the carbon-13 end of a C–H bond is in close spatial contact with a fluorine 2p lone pair. As illustrated in Figure 11 and Figure 12, respectively, this coupling can be attributed to the overlap of the fluorine lone-pair orbital with the CH bonding orbital, augmented by some overlap of the fluorine lone pair with the corresponding CH antibonding orbital. The orbital mixing that arises from this overlap of these three basis orbitals creates three three-center molecular orbitals in each case, a pair of filled bonding and antibonding orbitals that are involved in the through-space coupling, and also one high-energy antibonding orbital that is empty and therefore plays no role in coupling.

In the F...HC orientation, for which the two filled three-center orbitals σ_{FHC} and σ_{FHC}^* are depicted in Figure 11, the amplitudes of the wave functions are such that the electron density in the bonding σ_{FHC} orbital is concentrated mostly in the middle region of the three-atom array, whereas the electron density in the antibonding σ_{FHC}^* orbital is concentrated mostly at the ends of the three-atom array. The spin-polarization pattern of these two pairs of electrons that appears to lead overall to the most favorable combination of Hund and Fermi interactions in the F...HC system is shown in Figure 13(a). By analogy with the F–F system discussed in the preceding section, we believe that the σ_{FHC} electron will experience Hund interactions at the fluorine atom primarily with the outer region of the spin-polarized s_F orbital, and therefore will prefer to have its spin aligned parallel to the spin of the fluorine nucleus. Also by analogy with the F–F system discussed above, we believe that the σ_{FHC}^* electron will experience Hund interactions at the fluorine atom primarily with the inner region of the spin-polarized s_F orbital, and therefore will prefer to have its spin aligned antiparallel to

Figure 11 Schematic representations of the approximate shapes and relative energies of the three-center bonding and antibonding molecular orbitals, σ_{FHC} and σ_{FHC}^* , that result from the overlap of a $p_{F\sigma}$ lone-pair orbital with a σ_{HC} orbital and a σ_{HC}^* orbital in a system such as (6) or (8) in which the fluorine atom is crowded against the hydrogen end of the CH fragment

Figure 12 Schematic representations of the shapes and relative energies of the three-center bonding and antibonding molecular orbitals, σ_{FCH} and σ_{FCH}^* , that result from the overlap of a $p_{F\sigma}$ lone-pair orbital with a σ_{CH} orbital and a σ_{CH}^* orbital in a system such as (9) in which the fluorine atom is spatially proximate to the carbon end of the CH fragment

Figure 13 Schematic representations of the preferred relative alignments of electron spins and nuclear spins in two systems: (a) the F...HC system depicted in Figure 11, and (b) the F...CH system depicted in Figure 12

the spin of the fluorine nucleus. The hydrogen and carbon-13 nuclei in this system interact with the σ_{FHC} and σ_{FHC}^* electrons by direct Fermi contact, which results in a preference for an antiparallel alignment of nuclear and electron spins in the regions around each of these nuclei. This analysis leads to the overall prediction that with respect to the through-space components of the H–F and C–F coupling in this system the hydrogen and fluorine nuclei in the F...HC system will prefer to have parallel nuclear spins, while the carbon and fluorine nuclei and also the carbon and hydrogen nuclei will prefer to have antiparallel nuclear spins, as shown in Figure 13(a). This prediction is in accord with the experimental demonstrations in these F...HC systems that the H–F coupling constants are negative and the C–F and C–H coupling constants are positive.^{10,11,31}

In the F...CH orientation, for which the two filled three-center orbitals σ_{FCH} and σ_{FCH}^* are depicted in Figure 12, the electron density in the bonding σ_{FCH} orbital is once again concentrated mostly in the middle region of the three-atom array while the electron density in the antibonding σ_{FCH}^* orbital is concentrated mostly at the ends of the three-atom array. The spin-polarization pattern of these two pairs of

Figure 14 Top views of (a) the lowest-energy π orbital and (b) one of the σ orbitals of the basal trisubstituted benzene ring in phosphorus compound (15)

electrons that appears to lead overall to the most favorable combination of Hund and Fermi interactions in the F...CH system is shown in Figure 13(b). This analysis leads to the overall prediction that with respect to the through-space components of H–F and C–F coupling in this system the hydrogen and fluorine nuclei and also the carbon and hydrogen nuclei will prefer to have antiparallel nuclear spins, consistent with the experimental observations that the H–F and C–H coupling constants in these F...CH systems are each positive in sign. The pattern in Figure 13(b) also predicts that $J(FC)^{TS}$ in this system should be negative. In fact, the total coupling constant $J(FC)$ is found to be small and negative in a particular F...CH system similar to (9),¹¹ but in contrast $J(FC)$ is found to be positive in system (9) itself and other F...CH systems.³¹ Perhaps this discrepancy arises because the through-bond component of the C–F coupling in molecules such as (9) is positive in sign and sufficiently large in magnitude to override the small negative through-space component of the C–F coupling that is predicted by the analysis shown in Figure 13(b). Alternatively, perhaps that analysis is simply not a reliable basis on which to predict the sign of $J(FC)$ in such systems.

The recently reported novel through-space coupling between phosphorus and carbon-13 nuclei in molecules such as (15) has been attributed to overlap interactions involving the lowest-energy π orbital of the basal trisubstituted benzene ring shown in Figure 14(a).^{16,17} This π orbital has the proper symmetry to mix with the lone-pair orbital on the phosphorus atom to generate two new filled seven-center molecular orbitals, one bonding and the other antibonding in the region between the phosphorus atom and the benzene ring. As an alternative possibility for consideration we suggest that the observed P–C coupling in (15) might involve mixing of the phosphorus lone-pair orbital with the σ orbital of the basal benzene ring shown in Figure 14(b). This mixing would generate a bonding and antibonding pair of filled 13-center molecular orbitals.

5 HH SYSTEMS

Having considered above how through-space coupling can be viewed as arising mainly from overlap interactions between two lone pairs or between one lone pair and one bond pair, it remains to consider the through-space coupling that arises from overlap interactions between two bond pairs. The large 18 Hz coupling between the two bridgehead hydrogen atoms in bicyclo[1.1.1]pentane (10) can be attributed to such interactions.^{12,13} As shown in Figure 15, the mutual overlap of the rear lobes of the two filled C–H bond orbitals σ_{CH} and

Figure 15 Schematic representations of the approximate shapes and relative energies of the four-center bonding and antibonding molecular orbitals, σ_{HCCH} and σ^*_{HCCH} , that result from the overlap of two filled CH bond-pair orbitals (with slight admixture of the corresponding two empty CH antibonding orbitals that are not shown explicitly here) oriented with their carbon ends spatially proximate as for the bridgehead C–H bonds in bicyclo[1.1.1]pentane (10)

Figure 16 Schematic representations of the preferred relative alignments of electron spins and nuclear spins in the HC ... CH system depicted in Figure 15

σ'_{CH} , modified slightly by overlap interactions of these filled orbitals with the empty antibonding orbitals σ^*_{CH} and σ^*_{CH} , would give rise to two new four-center molecular orbitals, one bonding and the other antibonding. This orbital mixing creates a four-center four-electron HCCH linkage for the transmittal of nuclear spin information among the four nuclei. As illustrated in Figure 16, this analysis correctly predicts a positive sign for $J(HH)$ in bicyclo[1.1.1]pentane (10).

One could imagine that through-space H–H coupling also might result when the hydrogen ends of two C–H bonds are brought into close proximity with one another. Many examples of through-space H–H couplings in this latter type of orientation have been reported, but they are very small in magnitude.

6 F–F COUPLING THROUGH NONBONDED INTERACTIONS WITH AN INTERVENING ORBITAL

Finally, the lone-pair overlap theory has proved itself to be useful by predicting the existence of a new type of through-space F–F coupling in which the two coupled fluorines are not crowded directly against one another but rather are each crowded in a nonbonding way against an intervening group X in molecules such as 1,8-difluoro-9-X-anthracenes.³² For example, various 1,8-difluoro-9-phenylanthracenes show values of $J(FF)$ in the range of 5–6 Hz as compared with

Figure 17 Schematic representations of the three mixed orbitals thought to be involved in through-space F–F coupling in the 1,8-difluoro-9-phenylanthracene system

$J(FF)$ values of less than 1 Hz for the corresponding 1,8-difluoroanthracenes.^{9,32} As a result of the steric demands in this system the phenyl group is oriented with its plane perpendicular to the plane of the anthracene ring. The pathway for the transmission of nuclear spin information in this system is believed to result from the overlap interactions of three basis orbitals, including two fluorine lone-pair orbitals and the lowest-energy filled π orbital on the intervening phenyl group. These interactions generate a set of three mixed orbitals, including one three-center bonding orbital σ_{FXF} , one three-center nonbonding orbital n_{FXF} , and one three-center antibonding orbital σ^*_{FXF} as in Figure 17. The lowest-energy π orbital is expected to have the most effective interactions here because ab initio molecular orbital calculations indicate that its energy is very close to that of the fluorine lone-pair orbitals.⁹ In addition, however, other π and π^* orbitals on the phenyl that possess the correct symmetry for overlap with the fluorine orbitals also may play a role in the F–X–F coupling.

1 INTRODUCTION

Conventional crystallographic representations of molecules in solids give the impression that the molecules are held rigidly in place in the crystal as static motionless bodies. However, molecules and their component groups and atoms are certainly not motionless in solids. Molecules in solids are dynamic entities with a wide range of different molecular motion types.

Although most types of molecular motion are generally slower in solids than in liquids, they may have an important role in determining the macroscopic properties of solid materials. This applies to all solids irrespective of their degree of crystallinity. For example, the mechanical properties of important materials such as polymers are closely related to their microscopic structures and molecular motions. In addition, the conductivity of solid polymer electrolytes and the electrical properties of conducting polymers originate from motions at the molecular level. It becomes important, therefore, to gain an understanding of the nature of these motions in all types of solids and their relative rates and activation energies.

Several physical techniques can be employed to examine these molecular dynamics including the measurement and interpretation of anisotropic displacement parameters from diffraction techniques, Raman scattering, Brillouin scattering and dielectric relaxation. However, the most versatile technique is NMR spectroscopy. NMR is particularly powerful because by judicious choice of the nucleus to be observed and the NMR technique to be employed a wide range of time scales for molecular motions are available.¹ A general rule of thumb is that if the frequency, or time scale for a nuclear interaction is similar to that of the molecular process occurring, the molecular process will modulate the NMR interaction, which

will give rise to an observable effect in most cases. Since many more NMR interactions are present in solids than in solution (where they are averaged to zero by rapid isotropic molecular tumbling) observation of molecular motions in solids is greatly facilitated. Moreover, both broad line (static samples) and high resolution (magic angle spinning) methods are available. Such processes have included, but are not restricted to, rotations or displacements of whole molecules; segmental motions in polymer chains; conformational dynamics in molecules such as bond rotations, ring inversions and pseudorotations; molecular rearrangements such as sigmatropic rearrangements and dynamic tautomerism; and hydrogen bond exchange processes.

An alternative way in which NMR can be used to measure the kinetics of molecular processes is to create a magnetic label at one site (chemical shift) and watch it being transferred to another. Such methods include inversion and saturation transfer and 2D EXSY spectroscopy. These measurements are made in real time and consequently their time scale is dependent on the nuclear relaxation times involved. This article reviews several diverse applications of solid-state NMR spectroscopy falling into the categories described above. Table 1 summarizes the major methods, their origins, and the typical rate ranges that they can be employed to study.

It is interesting to compare the kinetics of processes happening in the solid state with those observed in solution. In many cases involving conformational rate processes the rates in solids are considerably slower than those observed in solution. This is because of the additional constraints imposed upon such process by the neighboring molecules in the lattice. These constraints are not present in solution leading to lower energies of activation. This effect has been referred to as the principal of least distress.³ On the other hand for intramolecular tautomerization processes in which hydrogen atoms travel short distances such effects are negligible.

2 LINE SHAPE METHODS

Line shape methods have been used extensively in high resolution solution state NMR for many years, and are also available in solids under conditions of magic angle spinning (MAS). In particular ^{13}C CP/MAS NMR has yielded much useful information. Line shape effects occur in the exchange region where the chemical shift difference between sites in a molecule is of the same order as the rate at which they are exchanging. The basic theory for these effects was given by McConnell,² and often the modified Bloch equations are used for line shape calculations. Many computer programs are available for line shape calculations.

(1)

Table 1 Widely used methods for studying dynamic processes in solids

Method	Approximate rate range	Outcomes
T_1	Near Larmor frequency 10^6 – 10^9 Hz	Frequency of motion
$T_{1\rho}$	Near spin lock frequency 10^3 – 10^6 Hz	Frequency and often mode of motion
Line shape	Near chemical shift difference 10 – 10^4 Hz	Frequency of motion
2D EXSY	Near $1/T_1$ 10^{-2} – 10 Hz	Frequency of motion
Magnetization transfer	Near $1/T_1$ 10^{-2} – 10 Hz	Frequency of motion
^2H quadrupole echo spectra	Near quadrupole coupling constant 125 –kHz	Frequency and often mode of motion

Line shape changes due to dynamic effects in ^{13}C CP/MAS spectra are illustrated very simply in Figure 1.³ The changes arise from the *t*-butyl group rotation in (1). At low temperatures rotation of the *t*-butyl group is slow (i.e., rate of rotation is $\ll \delta\nu(\text{Hz})$) and three methyl resonances are seen. The coalescence of the three methyls into a single peak is observed at around 293 K ($\Delta G_c^\ddagger = \text{ca } 55 \text{ kJ mol}^{-1}$). The solution state coalescence takes place at approximately 183 K ($\Delta G_c^\ddagger = \text{ca } 38 \text{ kJ mol}^{-1}$). The lifting of the degeneracy of two of the methyl groups in solution is due to molecular dissymmetry in the crystal lattice. The increase in the activation energy by around 17 kJ mol^{-1} is due to the additional constraints imposed upon the process in the solid by the neighboring molecules.

An alternative, both in the nucleus employed and the result obtained, is seen in Figure 2.⁴ This shows the line shape changes in the ^{15}N CP/MAS spectra due to hydrogen exchange between the nitrogens in the porphyrin anion (2) encased in a solid matrix. In contrast to the example given above the degeneracy of the exchange seen in solution is not lifted in the solid state with only three ^{15}N resonances being observed. The rates of hydrogen transfer are very similar to those determined in solution. In this case there is no effect from neighboring molecules as the exchange is buried deep inside the molecule.

An example of six-membered ring inversion between two unequal sites is seen in Figure 3.⁵ In this case the dynamic spectral effects arise from ring inversion of cyclohexanol encased in a thiourea inclusion compound and were obtained by a ^{13}C single pulse MAS technique not CP/MAS. The smaller set of peaks in the low temperature spectra arise from the axial conformation. The free energy of activation for the ring inversion process (51 kJ mol^{-1} (eq to ax)) and the free energy difference (ca. 2.5 kJ mol^{-1}) are close to those observed for the compound in non-hydrogen bonding solvents (50 kJ mol^{-1} (eq to ax)) and (ca. 2.1 kJ mol^{-1}). Interestingly for several other mono-substituted cyclohexanes in thiourea inclusion compounds very different conformational parameters are obtained from those of the molecules free in solution.

In the above examples there were no spinning side bands in the high resolution solid state ^{13}C spectra. Where there is a spinning sideband manifold, line shape analysis in principle

requires consideration of the whole sideband pattern and not just the peaks at the isotropic chemical shifts. This is seen in a ^{13}C CP/MAS study of the sigmatropic Cope rearrangement of bullvalene in the solid state.^{6,7} Because the crystal structure of bullvalene as determined by X-ray crystallography is very highly ordered it was originally thought that the Cope rearrangement was not taking place in the solid. However, NMR studies have shown that in the solid state the molecule of bullvalene undergoes a sigmatropic rearrangement followed by a reorientation to regain the original molecular orientation in the solid. This process is given the rate constant k_c . Accompanying this process is a 3-fold rotation of the molecules as a distinct process given the rate constant k_r . These processes are shown in Figure 4 and the observed CP/MAS spectra are shown in Figure 5.

If the rotation were the only process the resonance for C4 would remain unaffected. The fact that this line broadens less rapidly than the others as the temperature is increased indicates the existence of the two processes and the line shape patterns at varying temperatures can be fitted to a process involving the two rate constants k_c and k_r . It should be noted that the spinning sidebands are observed for the superimposed resonances of C2 and C3 and that these form part of the coalescence pattern. Extracted Arrhenius activation energies for the Cope rearrangement and the three-fold rotation are found to be 63 and 88 kJ mol^{-1} respectively.

3 SPIN LATTICE RELAXATION TIME METHODS

Spin lattice relaxation, designated by the relaxation time T_1 , and relaxation in the rotating frame, designated by the relaxation time T_1 can form excellent probes for molecular motions in very different regions of molecular dynamics. The stimulation of NMR transitions at the heart of these relaxation processes occurs when the nucleus interacts with fluctuating fields inside the sample. There are two important fluctuating fields. The first is a fluctuating magnetic field that can interact with the nuclear magnetic moment. The second is a fluctuating electric field gradient (EFG) that can interact with the electric quadrupole moment of the nucleus (if it possesses one). Only quadrupolar nuclei ($I > 1/2$) have electric quadrupole moments. In all cases the frequency of the fluctuating field must be at or close to the field in which the nuclei are held. In addition, the exchange process to be studied must be the exclusive or principal cause of the nuclear relaxation.

For heteronuclei three cases can be identified: (i) static powders, (ii) powders being spun at the magic angle, and (iii) powders where longitudinal relaxation is isotropically

Figure 1 125.758 MHz ^{13}C line shape changes at variable temperature for (1) in the solid (CP/MAS) (lower set) and solution states. The changes are due to rotation of the *tert*-butyl group. Reproduced with permission from Ref.⁵

averaged by magnetization transfer. In (i) relaxation is multi-exponential and consequently difficult to evaluate. In (iii) relaxation is truly exponential with a single relaxation time T_1 , which is related in a straightforward way to the dipolar interaction(s) and the equilibrium and rate constants, but this is experimentally very difficult to obtain. In contrast (ii) represents an ideal compromise – relaxation is quasi exponential and is governed to a good approximation by the dipolar interaction(s), rate and equilibrium constants. Rates of ultrafast exchanges can be measured by this technique. For example, this technique was employed by Hoelger et al.⁸ to study the hydrogen exchange dynamics in ^{15}N labelled dimethyldibenzyltetraaza[14]annulene (see Figure 6).⁸ The hydrogen transfer rates that were measured were in the range 10^6 – 10^8 s $^{-1}$.

Cross polarization is often used to generate the magnetization needed for T_1 measurements for ^{13}C or ^{15}N , for example. Under these circumstances the pulse sequence of Torchia is in widespread use.⁹ In this sequence for ^{13}C the ^{13}C magnetization is generated in an enhanced form by a cross polarization sequence and then an inversion recovery type sequence is used to follow the recovery of the magnetization as a function of time. During the evolution period the ^1H nuclei are decoupled by continuous phase irradiation to avoid the possibility of their dephasing the ^{13}C magnetization. The FID is then collected accompanied by high power ^1H decoupling.

For ^1H in organic solids the spins are strongly coupled via a spin diffusion process and consequently all have the same T_1 value. Thus no information about specific sites can be obtained even if separate peaks for these sites can be seen by special spectral techniques, for example CRAMPS.

Figure 3 125.758 MHz ^{13}C line shape changes due to ring inversion of cyclohexanol in a thiourea inclusion complex (single pulse MAS spectra). Reproduced with permission from Figure 2 in Ref.⁵

This greatly decreases the utility of ^1H T_1 measurements for characterizing molecular motions. They have, however, been applied in simple cases in which all the protons are equivalent such as molecular rotation in benzene.

For ^2H T_1 is the most unambiguous relaxation time as it depends exclusively on molecular motion. The relaxation of quadrupolar nuclei such as ^2H depends upon the interaction between the quadrupole moment of the nucleus and the electric field gradient it experiences. Fluctuating electric field gradients produce spin lattice relaxation of the ^2H nucleus and the correlation time for molecular motion can be inferred if details of the quadrupole interaction are known. Modulation of the electric field gradient in molecular solids is usually produced by rotational or segmental motions. This technique has proved of particular value in chain-like structures, e.g., polymers or lipids where selective deuteration along the chain can characterize the motion of different segments. Measurement of ^2H relaxation times for broad powder patterns can be troublesome and is often best achieved by a saturation recovery technique using the pulse sequence of Hirschinger et al.¹⁰

For powder samples, however, its interpretation is complicated by the anisotropy of T_1 because the relaxation time depends upon the orientation of the unique principal axis (C–D bond) with respect to the external magnetic field. This means that different parts of the sample relax with different rates. Fortunately, in general, this effect is small and the powder average T_1 often describes the relaxation process in the crystal satisfactorily.¹¹

For the spin-lattice relaxation of ^2H the dependence of T_1 on the correlation time is given by

$$\frac{1}{T_1} = C \left\{ \frac{\tau_c}{1 + \omega_o^2 \tau_c^2} + \frac{4\tau_c}{1 + 4\omega_o^2 \tau_c^2} \right\} \quad (1)$$

Two regions occur depending on the magnitude of the correlation time. On the low temperature side of the T_1 minimum the rate of the molecular motion is slower than at the minimum, i.e., $\omega_o \tau_c \gg 1$. Combining equation (1) with the Arrhenius equation, it can be seen that the natural logarithm of the spin-lattice relaxation time depends on inverse temperature

$$\ln(T_1) = \frac{E_a}{RT} + \ln \left\{ \frac{\omega_o^2 A}{2C} \right\} \quad (2)$$

On the high temperature side of the minimum the motion is faster than at the minimum, i.e., $\omega_o \tau_c \ll 1$

$$\ln(T_1) = \frac{E_a}{RT} - \ln(5CA) \quad (3)$$

Thus in both cases the Arrhenius activation energy (E_a) can be obtained from the slope of a plot of $\ln(T_1)$ vs $1/T$.

In certain cases, however, there is also a dependence of T_1 upon the amplitude of the motion. In these cases the parameter E_a is called the apparent activation energy.

4 MAXIMUM DIPOLAR BROADENING

In high resolution CP/MAS NMR, ^1H dipolar decoupling is extensively used to remove any remaining dipolar and J coupling from ^1H to heteronuclei. Invariably this is done by a single frequency placed near the centre of the ^1H resonance. Typical values for the dipolar decoupling field are in the region 50–100 kHz. If there is a molecular motion or exchange taking place at or near this frequency it can interfere with the efficiency of the decoupling and this causes an increase in the line widths of the affected resonances. This effect was first noted by Rothwell and Waugh.¹² In effect the frequency of the incoherent molecular motion is interfering with the coherent decoupling field reducing its efficiency and broadening the line. Maximum dipolar broadening is most often observed as an increase followed by a reduction in line width as the

Figure 4 The sigmatropic rearrangement and rotational processes in solid bullvalene that give rise to the dynamic spectral changes seen in Figure 5. Reproduced with permission from Figure 1 in Ref.⁶

Figure 5 75.47 MHz ^{13}C CP/MAS spectra at variable temperature arising from the dynamic processes inside solid bullvalene illustrated in Figure 4. Reproduced with permission from Figure 2 in Ref.⁶

temperature is varied. A single rate constant at the temperature of maximum broadening may be extracted in the region $5\text{--}10 \times 10^4 \text{ s}^{-1}$.

An example of the use of maximum dynamic broadening may be found in work by Twyman and Dobson.¹³ They showed that a combination of line shape analysis, maximum dipolar broadening and magnetization transfer could be used to study the phenyl rotation in the compounds (3) and (4) over a wide range of rates of rotation.

5 $T_{1\rho}$ MEASUREMENTS

Maximum dynamic broadening is, however, generally not the best way to study molecular motions in this frequency range in CP/MAS spectra. Measurements of $T_{1\rho}$ are generally superior.¹⁴ In the $T_{1\rho}$ experiment the magnetization to be studied is flipped from equilibrium through 90° to take the magnetization into the $x'y'$ plane, where it is spin locked along a particular axis.¹⁵ Thus a $90^\circ + x'$ pulse placing the magnetization onto the $+y'$ axis would be followed by a spin lock field (ω_1) (ca. 50–100 kHz) being applied along the y' axis. The time course of the decay of the spin locked magnetization gives the relaxation rate in the rotating frame with time constant $T_{1\rho}$. In general the 90° pulse would be applied by a cross polarization sequence in which the ^1H and X nucleus fields are matched. The same fields would be used for spin locking (X) and for decoupling (^1H). This makes the $T_{1\rho}$ method sensitive in the same region as maximum dipolar broadening.

In principle the spin lock frequency can be varied to probe different rates of molecular motion. In practice dynamic information is more readily obtained by following the variation of $T_{1\rho}$ with temperature than by varying the spin lock field.

^{13}C $T_{1\rho}$ can be modulated both by molecular motions and by the ^1H spin diffusion process

$$\frac{1}{^{13}\text{C } T_{1\rho}} = \frac{1}{^{13}\text{C } T_{1\rho \text{ spin lattice}}} + \frac{1}{T_{\text{CH}}(\text{ADRF})} \quad (4)$$

Figure 6 The ultrafast hydrogen bond exchanges in dimethyldibenzotetraaza[14]annulene studied by ^{15}N T_1 relaxation methods

^{13}C $T_{1\rho}$ spin lattice arises from modulation of the spin locking field by the molecular motion. $T_{\text{CH}}(\text{ADRF})$ comes from modulation of the dipolar interaction by the spontaneous rigid lattice proton fluctuations (spin diffusion). In practice the latter effects are generally found to be negligible with spin locking fields in excess of ca. 35 kHz. Also in practice $T_{1\rho}$ measurements in CP/MAS NMR are generally made with spin lock fields that are the same as those used for cross polarization and are 50 kHz or greater.

For a dipolar interaction between two unlike spins, e.g., ^{13}C and ^1H

$$\frac{1}{T_{1\rho}} = \frac{B^2\tau}{(1 + \omega_1^2\tau^2)} \quad (5)$$

where ω_1 is the frequency of ^{13}C in the spin lock field, τ is the rotational correlation time for the molecular motion causing the relaxation (rotational correlation time), and B^2 is a measure of the ^{13}C – ^1H dipolar interaction.¹⁶ B^2 may be calculated for a particular model of motion and geometry from the equation given by Abragam.¹⁷ The rate of the molecular motion will vary with temperature T and therefore $T_{1\rho}$ will have a temperature dependence. Equation (5) predicts that $T_{1\rho}$ will have a minimum at the temperature at which $\omega_1\tau = 1$.

Hence at the minimum value of $T_{1\rho}$, $\omega_1\tau = 1$ and B^2 conforms to

$$B^2 = \frac{2}{(T_{1\rho})_{\min}\tau} \quad (6)$$

Thus the minimum value of $T_{1\rho}$ allows an experimental determination of B^2 . Two things follow from this. First the values of τ at each temperature may be extracted by solving the appropriate quadratic equation. Secondly the mode of motion may be checked by comparison of the calculated and experimental values of B^2 .¹⁸

The use and validity of $T_{1\rho}$ methods is illustrated in a study of the rotation of both *tert*-butyl groups in (5). Line shape analysis in the temperature range 202–233 K and $T_{1\rho}$ measurements in the temperature range 224–320 K were carried out.

If the reductions in ^{13}C $T_{1\rho}$ in the *tert*-butyl groups arise from group rotations then four predictions can be made.

- Both the central and the methyl carbons in the same *tert*-butyl group should show $T_{1\rho}$ minima at the same temperature.
- For a constant geometry of *tert*-butyl groups the $T_{1\rho}$ minima should be the same for both groups.

Figure 7 Observed (a) and calculated (b) 76.773 MHz ^2H quadrupole echo spectrum of 1,1,6,6- d_4 -hexane-1,6-diyl bis(*p*-nitrobenzoate) at varying temperatures. The changes arise from librational motions of the CD_2 groups. Refocusing delays are 20 (a) and 120 μs (b). Reproduced with permission from Figure 6 in Ref.²⁰

- Rate constants determined from the $T_{1\rho}$ data and the line shape analyses should fall on the same Eyring or Arrhenius plots.
- Experimentally determined B^2 values for the methyl and quaternary carbons should agree with those derived from calculation.

All four predictions are found to be correct.¹⁶

The same group went on to examine a wide variety of molecular motions in crystalline organic compounds including the related rotations of trimethylammonium and trimethylphosphonium groups. Interestingly and satisfyingly for the trimethylphosphonium group the data from the ^{13}C line shape changes, the ^{13}C $T_{1\rho}$ data and the ^{31}P $T_{1\rho}$ data all fitted the same activation plot.¹⁹

One further important point about $T_{1\rho}$ methods is that the measure of the dipolar interaction B^2 depends upon the geometry of the molecular motion.¹⁷ In principle this allows differentiation between alternative models for the molecular motion. For example, in *trans*-1,2-cyclopentanediol this method allowed a differentiation to be made between a whole molecule rotation process and an internal ring pseudorotation process with the latter process being the more likely origin of the experimental measurements.¹⁸

6 ^2H QUADRUPOLE ECHO METHODS

^2H quadrupole echo line shape studies have been perhaps the widest used NMR technique for studying molecular motions in solids. Although ^2H incorporation in the molecule is required the technique has the compensation that information about both the frequency and geometry of the molecular motion can be obtained. Typically ^2H spectra of solids are a few hundred kilohertz wide. In the absence of molecular motions the spectrum is a Pake

doublet with the horns of the pattern separated by the quadrupolar coupling constant. For a C–D bond this is ca. 125 kHz. As the frequencies of the molecular motions approach the value of the quadrupolar coupling constant the line shape changes. Figure 7 shows typical changes in the quadrupole echo spectra for 1,1,6,6- d_4 -hexane-1,6-diyl bis(*p*-nitrobenzoate) (6).²⁰ The line shape depends upon the motion of the C–D bond and can be calculated on the basis of frequency of the molecular motion and various possible geometric modes that are possible.²¹ Conclusions can then be drawn.

With line shapes of this width the free induction delays can be very short and some or all of the FID can be lost in the receiver dead time delay. This would lead to weak and distorted signals. To overcome this the quadrupole echo sequence is used in which a second $\pi/2$ pulse is applied in quadrature with the first at time τ . This results in refocussing of the magnetization and the formation of an echo at approximately 2τ after the first pulse.²² By starting the FT at the echo maximum one does not need to worry about signal that has been lost during the receiver dead time and undistorted spectra may be obtained.

An additional complication is that artifacts can be caused by the finite length of the $\pi/2$ pulse width. This can lead to uneven excitation of the spectrum, to a feed through signal or to a virtual FID. Fortunately the program MXET1 that is most often used for the simulation of 2H quadrupolar echo spectra includes a correction factor for the $\pi/2$ pulse width meaning that correct spectra can be calculated.²³

Finally, for a more certain assignment between different models of motion it is important that spectra are measured with different refocusing delays for comparison with simulated spectra. With longer delays more spectral intensity is lost and the measurement of quadrupole echo spectra in the intermediate exchange regime can become very time consuming for long refocusing delays since the echo intensity decays exponentially with the refocusing delay. In addition to the motional effects (T_2) in the intermediate exchange region the echo intensity is also decreased by dipolar couplings between deuterons and protons as the quadrupole echo sequence fails to refocus these couplings. Dipolar couplings also broaden the line shape and their effect can be taken into account by multiplying the free induction decay by a Gaussian broadening function that is a few kilohertz wide. Such a broadening has a fairly small effect on the line shape but the decrease in the echo intensity during the refocusing delay is considerable. For refocusing delays of 20 μ s and 160 μ s and an effective 2 kHz broadening it can be shown that the effect is an echo reduction of 0.67, and for an effective 3 kHz broadening the corresponding reduction would be 0.40. Thus, dipolar couplings reduce the echo intensity to about half its original intensity in addition to the T_2 effects in the intermediate exchange region. Thus for delays of 20 μ s and 160 μ s an echo reduction factor of ca. 0.5 is expected. If the echo reduction factor falls below this it is indicative of T_2 effects becoming important during the refocusing delay. If the echo reduction factor is greater than this it seems likely that the dipolar couplings between deuterons and protons are becoming less important. Either way an additional pointer is given to assist interpretation.²⁴ Figure 7 shows the effect of the echo reduction factor in the quadrupole echo spectra of 1,1,6,6-d₄-hexane-1,6-diyl bis(*p*-nitrobenzoate) (6).

The angle of the C–D bond motion can be measured directly from a two-dimensional deuterium exchange experiment.²⁵ In the absence of molecular motion the 2D exchange spectrum consists of a Pake doublet along the diagonal. Molecular motions in the slow exchange regime where the correlation time is longer than a millisecond induce intensity off the diagonal. These off-diagonal ridges are very characteristic to motional modes and also in favourable cases allow direct measurements of the angle of the C–D bond motion to be made. Slowly moving deuterons, however, tend to relax very slowly and so in the absence of any additional relaxation modes these long relaxation times can make this technique very time-consuming.

7 MEASUREMENT OF TEMPERATURE IN MAS EXPERIMENTS

The establishment of temperatures in MAS NMR experiments is an important but difficult problem.²⁶ It is important

because accurate temperatures are needed if activation parameters are to be determined for a particular process. It is difficult because it has been demonstrated by several groups that MAS causes the sample to heat. This heating is probably due to friction. It has been proposed and demonstrated that the heating varies with the square of the spinning speed.^{26,27} Thus, at high spinning speeds careful temperature calibration becomes even more important. Several methods have been proposed for the measurement of sample temperatures. Probably the most reliable is to follow accurately known phase changes that show changes in the spectra through the transition.²⁶ Using this method it is possible to reliably calibrate a probe/temperature controller combination.

1 INTRODUCTION: SPECIAL PROBLEMS

Since the early days of NMR, ^{19}F has been recognized as one of the most useful nuclei, and it has been widely studied for liquids and solutions. This is because it is present in 100% natural abundance, has a relatively high resonance frequency (near to that of the proton), and has a spin quantum number of $1/2$. These properties convey very favorable sensitivity in the NMR experiment – the receptivity is 83.4% of that for ^1H and 4.90×10^3 of that for ^{13}C . Moreover, the chemical shift range for ^{19}F is comparable to that of, say, ^{13}C and well over an order of magnitude greater than that for ^1H . It follows that, of the obvious nuclei used to examine fluorinated systems containing hydrogen by NMR, fluorine will often be preferred. However, although there have been a number of reports of ^{19}F relaxation parameters and broadline spectra of solids containing fluorine, the use of high-resolution ^{19}F spectra for studying such systems has been relatively limited. Indeed, until relatively recently the total amount of high-resolution ^{19}F NMR work on solids of all types was surprisingly small. It has been reviewed twice in the past decade.^{1,2} This lack of

reported work is particularly marked for systems containing both fluorine and hydrogen, which form the special topic of this article.

Paradoxically, the reasons for the relative lack of activity on ^{19}F are two of the major advantages of the nucleus, namely the 100% natural abundance and its high magnetic moment. These imply that dipolar interactions (both homonuclear and heteronuclear) are likely to be very strong. The present review will be largely limited to (^{19}F , ^1H) double resonance studies, usually involving ^{19}F magic-angle spinning (MAS) spectra obtained with proton decoupling. Associated relaxation time measurements, some related static experiments and some very-high speed MAS investigations will also be covered. Such experiments give improved quality of spectra for both static and magic-angle spinning experiments (especially yielding higher resolution for the latter), and also simplify the interpretation of relaxation data. Also, additional experiments become feasible from the $^1\text{H} \rightarrow ^{19}\text{F}$ cross-polarization operation. However, the excitation bandwidth required for ^{19}F spectra, especially for high-field spectrometers, is a further source of experimental problems – for example, at 11 T, 100 ppm, which is insufficient for most spectra, is the equivalent of 47 kHz.

All the early ^{19}F NMR work on solid fluorinated systems that also contain hydrogen involved measurements of ^{19}F relaxation and broadline spectra, using what are now thought of as ‘classical’ NMR techniques.^{3,4} Since proton decoupling was not generally employed, there are in principle complications in treating the experimental data which arise from cross-relaxation between ^{19}F and ^1H . This problem renders simple T_1 measurements (e.g., by inversion-recovery) intrinsically not single-exponential and raises questions about the influence of the nuclear Overhauser effect. Such issues were generally ignored in the early literature in this area, though they have been addressed by some authors.⁵ Of course, all the relevant work before the advent⁶ of the combined CPMAS suite of techniques in 1976 was based on low-resolution experiments. The data were interpreted in terms of dipolar interactions rather than chemical shifts and gave information on molecular-level mobility (and domain structure in polymers) rather than chemical structure.

However, there was a long delay following the development of CPMAS NMR before the new techniques were significantly employed for solid fluorinated materials which also contained hydrogen. This is because (^{19}F , ^1H) double-resonance experiments are significantly more difficult than analogous (^{13}C , ^1H) work, which is a result of the proximity of the resonance frequencies of ^{19}F and ^1H (within 6%). Since, for work on solids, decoupling protons from fluorines requires very high powers, there are obvious problems involving the efficiency of r.f. filtering, which inhibited developments. Moreover, without such filtering, $^1\text{H} \rightarrow ^{19}\text{F}$ cross polarization is not feasible, thus preventing a wide range of informative experiments from taking place. However, the NMR community was in general, perhaps, too timid in this matter, since the first commercial ^{19}F – $\{^1\text{H}\}$ probes suitable for solids were found to be very effective.^{7–11} Recently, it has been shown (see below) that very-high-speed MAS is often an acceptable alternative to ^{19}F – $\{^1\text{H}\}$ decoupling in moderate-speed MAS work.

Even with efficient ^1H decoupling, achieving high-resolution ^{19}F spectra of polyfluorinated systems presents difficulties because of the strong (^{19}F , ^{19}F) dipolar interactions, which require either multipulse homonuclear decoupling pulse

sequences (e.g., MREV 8) combined with modest-speed MAS (CRAMPS) or very fast (>20 kHz) MAS for their effective removal. Early work on both methods^{12,13} was directed at perfluorinated systems. The technical difficulties involved meant that there was only very limited use of these techniques for hydrogen-fluorine systems until the mid-1990s. The next section will show how the experimental situation has now dramatically changed.

2 SPECIAL TECHNIQUES AND EXPERIMENTAL REQUIREMENTS

The origin of the attraction of ^{19}F as a probe nucleus for NMR also results in the majority of the experimental difficulties. Both the dipolar coupling and the chemical shift anisotropy are first-order anisotropic interactions, which are most conveniently averaged by magic-angle sample spinning (MAS). However, when spinning speeds are modest (<20 kHz), as has always been the case until very recently, it is also essential to effectively eliminate the influence of H,F dipolar coupling (for chemical systems containing both nuclei) by the usual heteronuclear double-resonance techniques. However, in the early days of high-resolution solid-state NMR this was thought to be a difficulty (see below) so that substantial work in this area only started in about 1992. In more recent years, the development of high-speed MAS systems, allowing for spinning speeds in excess of 30 kHz, has rendered the acquisition of high-resolution solid-state ^{19}F NMR spectra of compounds containing both abundant protons and fluorines possible without proton decoupling.^{13–15}

However, MAS provides the same degree of line narrowing throughout the entire experiment, which is somewhat contrary to one of the major advantages of NMR, the possibility to manipulate and separate interactions. Therefore, even under high-speed MAS double-resonance experiments are desirable. Although proton decoupling leads to no significant resolution enhancement at such high speeds (though splittings arising from H,F isotropic indirect coupling are eliminated, resulting in some improvement), there is a general need for double-resonance experiments to manipulate the heteronuclear dipolar coupling for certain periods of the experiment. The application of high-speed (>20 kHz) MAS requires dedicated equipment that might not always be available. The low-volume rotors present possible difficulties for sample handling. For receptivity the small volume is not usually a problem (except for 'dilute' fluorine cases, such as compounds at interfaces), because the narrow lines from high-speed MAS result in good apparent signal-to-noise ratio. On the other hand, the small sample volume required in the high-speed MAS systems can be an advantage, when novel compounds, only obtainable in very small quantities, are investigated. The major advantage in the application of fast MAS, however, is the simultaneous averaging of the homonuclear fluorine–fluorine coupling, which can be strong in fluorine-rich systems (Figure 1). To follow the time development of any process (such as relaxation) in the experiment, rotor-synchronous detection is usually applied to exclude from the data analysis the additional time-dependence resulting from MAS.

The classical spectrometer design, based on an X channel, together with a proton channel mostly used for decoupling,

Figure 1 282 MHz fluorine-19 MAS NMR spectra of PVDF: (a) 32 kHz spin rate with no proton decoupling; (b) 16 kHz spin rate with proton decoupling; (c) 16 kHz spin rate with no proton decoupling; and (d) REDOR spectrum (mixing time 0.4 ms; 10 rotor cycles) with 32 kHz spin rate and proton decoupling

is inappropriate for proton–fluorine double-resonance experiments. Because the magnetogyric ratios of almost all X nuclei are lower than that of the proton by at least a factor of 0.4, the frequency range in the X channel of traditional spectrometers is limited. A flexible second channel is therefore needed for proton–fluorine double resonance. The same is true for the probe-head, since a typical H–X solid-state probe-head is based on a relatively large frequency separation. Usually, there is a high-frequency channel tunable to proton and fluorine, with an X channel that is also narrow-band but can be tuned to a wide range of frequencies. The separation/decoupling between the two RF channels is based on the large difference of the resonance frequencies of H and X.

The Larmor frequencies of proton and fluorine nuclei are separated by only 6%. Therefore, the standard double-resonance probe design is not applicable, so that a dedicated probe-head is required for proton–fluorine double resonance. The first reported proton-decoupled fluorine solid-state NMR

spectra were obtained^{8–11,16} using dedicated double-resonance probes. Such probes are based on traditional technology, with oscillators and transmission lines. They are specially made for the two frequencies and do not allow more extended tuning. Another option is the use of an overcoupling network, introduced by Maas et al.¹⁷ An additional oscillator inserted between the transmitter and the probe splits the high-frequency resonance of a traditional double-resonance probe symmetrically into two. While this setup was originally developed to achieve simultaneous proton and fluorine decoupling for ^{13}C -observe operation, it can also be applied for proton–fluorine double-resonance experiments. Appropriate external filtering also has to be employed. External RF filters are in any case needed to achieve the attenuation of more than 60 dB between the two channels that is necessary for the acquisition of any spectrum under high-power decoupling. Because the ^{19}F and ^1H frequencies are so close, filters of extremely narrow bandwidth have to be used. These filters may influence the rise and fall times of pulses.

The only known applications^{18,19} of proton–fluorine double-resonance experiments where no bandpass filters were in use are multiple-pulse experiments. In those experiments no decoupling pulse is present during data acquisition. Omitting external RF filters allows shorter pulses, because there is no bandwidth limitation and no insertion loss. The usual multipulse sequences such as WAHUA, MREV8 or BR24 are designed to average homonuclear dipolar coupling, which is bilinear in the spin operators. As a side effect they scale both the chemical shift and the heteronuclear dipolar coupling, which are each linear in the spin operators. Strong heteronuclear dipolar coupling (e.g., the coupling between protons and fluorine nuclei) results in an unacceptable linewidth. Therefore, heteronuclear decoupling has to be included, which is achieved by π pulses on the non-detected channel, synchronized with the multipulse sequence on the detection channel (Figure 2).

A minor additional problem appears in solid-state NMR probes dedicated to proton–fluorine double-resonance NMR: the question of probe background signals. Especially when variable-temperature experiments are required, there is little possibility to avoid both proton and fluorine-containing materials in capacitors and all structural materials in the sensitive part of the probe simultaneously. Therefore, usually one or the other has to be selected when designing/manufacturing the probe. Generally the acquisition of fluorine spectra is more desirable than that of proton spectra because of the information content in the larger chemical range of the former. However, in proton-detected experiments a background signal will then be present. The small chemical shift range of protons, however, permits detection at a small spectral width, where background signals from static solid material only show up as a minor baseline distortion.

Various experiments for background suppression have been proposed, such as composite pulses.²⁰ Another possibility is the excitation of fluorine magnetization via proton–fluorine cross polarization. Materials used in NMR probe manufacturing are usually perfluorinated and do not generate a ^{19}F signal from $^1\text{H} \rightarrow ^{19}\text{F}$ CP. Similarly, background-free ^1H spectra can be obtained by $^{19}\text{F} \rightarrow ^1\text{H}$ CP. However, both methods for background suppression introduce additional uncertainties for the experiment and usually inhibit quantitative analysis of

Figure 2 Combined rotational and multipulse experiments on a semifluorinated tetrapropyl-adamantane at 188.29 MHz: ^{19}F CRAMPS with synchronized pulses on the proton channel

the spectra, though they also allow additional useful measurements to be made. The preferable way is just to avoid the probe background signal for the experiment desired.

Of course, most of the pulse sequences used traditionally for $^1\text{H} \rightarrow ^{13}\text{C}$ CPMAS NMR (such as dipolar dephasing and two-dimensional HETCOR/EXSY) can be adapted to acquire $^1\text{H} \rightarrow ^{19}\text{F}$ CPMAS spectra, starting with the simple CP sequence (Figure 3a). For instance, the WISE sequence²¹ (Figure 3b) can be used²² to obtain ^1H bands with the chemical shift discrimination inherent in the ^{19}F spectrum. Usually the homonuclear F,F coupling requires fast MAS for resolution in the ^{19}F spectrum. Therefore, the ^1H band breaks up into spinning sidebands (ssb). The second moment of the ssb manifold contains valuable information on the residual dipolar coupling and can be used as a measure of mobility.²³ Moreover, various techniques can be applied^{24,25} to discriminate between well-resolved ^{19}F subspectra of different domains in heterogeneous solids, such as use of a ^1H spin-lock ($T_{1\rho}^{\text{H}}$) or ^1H inversion recovery or T_2^{H} decay (delayed contact) prior to CP (Figure 3c). Similarly, a post-CP ^{19}F spin-lock ($T_{1\rho}^{\text{F}}$) or T_2^{F} decay (delayed acquisition) can be used, as can a one-dimensional (fixed mixing time) REDOR sequence, radiofrequency-driven recoupling (RFDR), a dipolar filter, or DIVAM.²⁶ The result of a REDOR selection for the amorphous region of the ^{19}F spectrum of poly(vinylidene fluoride), PVDF,

Figure 3 Pulse sequences used for proton–fluorine double-resonance experiments: (a) cross polarization; (b) wideline separation; (c) cross polarization after selection of a sub-ensemble of the proton spins based on proton relaxation times. Possible filters are: dipolar filter, $T_{1\rho}^{\text{H}}$ filter, T_1^{H} filter; (d) WISE experiment for a sub-ensemble after selection by a magnetization filter

is shown in Figure 1(d). Of course, the simple CPMAS sequence with variable contact time is itself discriminatory, especially when compared to single-pulse excitation (SPE) with MAS. Spin-diffusion can be studied²⁷ using the Goldman-Shen²⁸ type of sequence, with appropriate filtering, and the WISE experiment can be combined with various filtering arrangements (Figure 3d). The results of a number of filtering experiments on polymer spectra are discussed in Section 4.

Besides the thermodynamic analysis of the cross polarization dynamics for multiple spin baths, which will be described in the following section, there is the possibility to break the complicated multi-spin system experimentally into a superposition of spin pairs without diluting the sample. This idea

makes use of the fact that in a spin-pair under cross polarization the magnetization oscillates between the two coupled spins (dipolar oscillation),^{26,29,30} which has been reported for rare cases. However, usually such isolated spin pairs are not present in the sample and the dipolar oscillations are smeared out because the homonuclear dipolar coupling results in spin diffusion. The dipolar oscillations are often ignored for the thermodynamic treatment of the cross-polarization experiment.

Under a spin lock at the magic angle (Lee–Goldburg experiment) the homonuclear dipolar coupling is readily suppressed.³¹ The heteronuclear dipolar coupling can be retained when simultaneously applying spin-lock fields at both frequencies to fulfil the Hartmann–Hahn condition.³² The inherent beauty of this technique lies in the fact that a complex network of dipolar couplings can be broken down to a superposition of pairwise couplings, which are easily interpreted. While this approach has been applied to a case of proton-carbon cross polarization,³³ preliminary studies of proton–fluorine Lee–Goldburg cross polarization have been reported.³⁴ The complication here is that the homonuclear coupling in both spin baths has to be suppressed. This requires the application of spin-locking at the magic angle on both channels, resulting in a magnetization oriented at the magic angle (which requires an additional read-out pulse). The experiments can be simplified again under fast MAS, where the lines in the fluorine spectrum are well separated anyway. Because the homonuclear coupling is scaled by a factor of (-2) under the spin lock, this appears to be sufficient in many cases. For an example (5-fluoro-2 trifluorobenzoic acid), the signals for the CF and the CF_3 fluorines are well-resolved under MAS.³⁵ For each fluorine site the internuclear distances to the various neighboring protons have been determined. When the matching is on the first spinning sideband of the Hartmann–Hahn condition, the detected coupling (and thus the distance) is independent of the sample spinning frequency. Because the easiest data evaluation is performed from rotor-synchronized detection, the range of dipolar couplings is limited, so that the maximum coupling that can be characterized is determined by the spinning speed. The distances determined using this approach correspond within experimental error to those obtained from structural molecular simulations.

3 CROSS POLARIZATION DYNAMICS BETWEEN ^1H AND ^{19}F

A phenomenological spin thermodynamics^{36–39} theory based on the spin-temperature hypothesis has been employed^{39,40} to analyze the cross polarization (CP) dynamics between fluorine and proton in solids. The inverse spin temperature β , which is defined as $\hbar/kT$, is proportional to the magnitude of magnetization in the case that only the Zeeman interaction is considered. The variations with time of the inverse spin temperatures, β_{H} and β_{F} for the H and F spin baths, are described within this framework. The two spin baths can be in contact with each other and coupled with the lattice, which is suggested to have an infinitely high heat capacity at β_{L} as depicted in Figure 4.

The rate of the polarization transfer from H to F spin baths is characterized by a time constant T_{HF} . Under the spin-lock condition in the presence of simultaneous rf fields of $B_{1\text{F}}$ for F and $B_{1\text{H}}$ for H, each link between a spin bath

Figure 4 Schematic representation of an abundant ^1H spin bath and an abundant ^{19}F spin bath, which are spin-locked by RF irradiation and coupled to the lattice as expressed by their spin-lattice relaxation times in the rotating frame, $T_{1\rho}^{\text{H}}$ and $T_{1\rho}^{\text{F}}$ respectively. The rates of polarization transfer between the two spin baths are represented by the cross-relaxation times T_{HF} ($\text{H} \rightarrow \text{F}$) and T_{FH} ($\text{F} \rightarrow \text{H}$). β is the inverse spin temperature, N the density of spins, γ the gyromagnetic ratio, and B_1 the RF field for spin locking

and the lattice is characterized by a spin-lattice relaxation time in the rotating frame, $T_{1\rho}^{\text{F}}$ for F and $T_{1\rho}^{\text{H}}$ for H. When there is a difference between β_{F} and β_{H} , polarization transfer occurs between H and F spins during the contact time (t_{CP}) of cross-polarization (CP) and TORQUE⁴¹ experiments. We assume that β in each spin bath is immediately equilibrated. Hence, oscillation of magnetization between H and F spins is neglected. Such phenomena can occur when there are strongly coupled H–F spin pairs. In addition, we consider only experimental situations where magic-angle spinning does not interfere with the CP process.

Assuming first-order kinetics, the variations of β_{F} and β_{H} under a cross-relaxation condition can be described by the coupled differential equations,

$$\begin{aligned} \frac{d}{dt}\beta_{\text{F}} &= -\frac{1}{T_{\text{HF}}}(\beta_{\text{F}} - \beta_{\text{H}}) - \frac{1}{T_{1\rho}^{\text{F}}}\beta_{\text{F}} \\ \frac{d}{dt}\beta_{\text{H}} &= -\frac{\varepsilon}{T_{\text{HF}}}(\beta_{\text{H}} - \beta_{\text{F}}) - \frac{1}{T_{1\rho}^{\text{H}}}\beta_{\text{H}} \end{aligned} \quad (1)$$

where ε is defined as

$$\varepsilon = \frac{N_{\text{F}}(\gamma_{\text{F}}B_{1\text{F}})^2}{N_{\text{H}}(\gamma_{\text{H}}B_{1\text{H}})^2} \quad (2)$$

The N and the γ are the number of spins and the gyromagnetic ratio for the indicated nuclear type, respectively. When the Hartmann–Hahn condition

$$\gamma_{\text{H}}B_{1\text{H}} = \gamma_{\text{F}}B_{1\text{F}} \quad (3)$$

is achieved, ε is equal to $N_{\text{F}}/N_{\text{H}}$. In the case of $\text{H} \rightarrow \text{F}$ cross polarization, equation (1) can be straightforwardly solved under the initial conditions ($t_{\text{CP}} = 0$):

$$\beta_{\text{F}} = 0 \text{ and } \beta_{\text{H}} = \beta_{\text{H0}} \quad (4)$$

The dependence of β_{F} on t_{CP} , which corresponds to an evolution of F magnetization as a function of contact time in the standard CP experiment (which we will refer to as a CP curve), can be expressed as follows:

$$\begin{aligned} \left[\frac{\beta_{\text{F}}(t)}{\beta_{\text{H0}}} \right]_{\text{CP}} &= \frac{1}{a_+ - a_-} \\ &\times \left[-\exp\left(-\frac{a_+}{T_{\text{HF}}}t_{\text{CP}}\right) + \exp\left(-\frac{a_-}{T_{\text{HF}}}t_{\text{CP}}\right) \right] \end{aligned} \quad (5)$$

where $a_{\pm} = a_0 \pm \sqrt{a_0^2 - b}$ (6)

with $a_0 = \frac{1}{2} \left(1 + \varepsilon + \frac{T_{\text{HF}}}{T_{1\rho}^{\text{H}}} + \frac{T_{\text{HF}}}{T_{1\rho}^{\text{F}}} \right)$ (7)

and $b = \frac{T_{\text{HF}}}{T_{1\rho}^{\text{H}}} \left(1 + \frac{T_{\text{HF}}}{T_{1\rho}^{\text{F}}} \right) + \varepsilon \frac{T_{\text{HF}}}{T_{1\rho}^{\text{F}}}$ (8)

In the same way, the dependence of β_{F} on t_{CP} in the $\text{H} \rightarrow \text{F}$ TORQUE experiments (which we will refer to as a TORQUE curve) can be expressed as

$$\left[\frac{\beta_{\text{F}}(t)}{\beta_{\text{H0}}} \right]_{\text{TOR}} = \exp\left(-\frac{t_{\text{SL}}}{T_{1\rho}^{\text{H}}}\right) \left[\frac{\beta_{\text{F}}(t)}{\beta_{\text{H0}}} \right]_{\text{CP}} \quad (9)$$

where t_{SL} is a spin-lock time for the H nuclei prior to the cross polarization to F nuclei.

Figure 5 shows⁴⁰ the calculated CP and TORQUE curves for $\varepsilon = 0.01$ and $\varepsilon = 1$. The constant spin-lock time for H spins, $t_{\text{const}} = t_{\text{SL}} + t_{\text{CP}}$, in the TORQUE curves is 5.0 ms, and the values of β_{F} are normalized at $t_{\text{CP}} = t_{\text{const}}$ in order to compare the shapes of the curves. T_{HF} was kept constant at 0.5 ms, and the relaxation parameters for the various curves used were: (A) $T_{1\rho}^{\text{H}} = 2.5$ ms, $T_{1\rho}^{\text{F}} = 100$ ms, (B) $T_{1\rho}^{\text{H}} = 2.5$ ms, $T_{1\rho}^{\text{F}} = 2.5$ ms, (C) $T_{1\rho}^{\text{H}} = 5.0$ ms, $T_{1\rho}^{\text{F}} = 5.0$ ms, (D) $T_{1\rho}^{\text{H}} = 100$ ms, $T_{1\rho}^{\text{F}} = 2.5$ ms. The CP curves for $\varepsilon = 0.01$ (Figure 5a) correspond to a typical case of $^1\text{H} \rightarrow ^{13}\text{C}$ CP or to $^1\text{H} \rightarrow ^{19}\text{F}$ CP for materials that are chemically dilute in fluorines but have abundant protons. In this case, it is well known that the decaying slope of the CP curves in a logarithmic scale is principally determined by $-1/T_{1\rho}^{\text{H}}$ in the region where $t_{\text{CP}} \gg T_{\text{HF}}$, and the influence of $1/T_{1\rho}^{\text{F}}$ on the slope is negligible. This indicates that different $T_{1\rho}^{\text{H}}$ s can be potentially discriminated from the decaying slope of CP curves when ε is much smaller than 1. When the number of fluorine atoms is much smaller than that of ^1H in organic molecules, there is no effective direct relaxation path from ^{19}F to the lattice under spin-locked conditions. As a result, the heat capacity of the ^{19}F spin bath is negligibly small, and $T_{1\rho}^{\text{F}}$ is generally much longer than $T_{1\rho}^{\text{H}}$.

On the other hand, the CP curves for $\varepsilon = 1$ (Figure 5b) correspond to a more typical case of $^1\text{H} \rightarrow ^{19}\text{F}$ CP with both hydrogen and fluorine in high concentration, because ^{19}F has 100% natural abundance. For example, the $N_{\text{F}}/N_{\text{H}}$ of one of the most popular fluoropolymers, poly(vinylidene fluoride), is 1. These curves show significantly different behavior from those in Figure 5(a). In particular, no difference was observed in the curves of A, C, and D in spite of the large differences in their values of $T_{1\rho}^{\text{H}}$ and $T_{1\rho}^{\text{F}}$. This can be explained by the fact that the decaying slope is principally determined

Figure 5 Evolution of the inverse spin temperature (β) for the F bath in the standard $H \rightarrow F$ CP experiment for (a) $\varepsilon = 0.01$ and (b) $\varepsilon = 1$ and in the $H \rightarrow F$ TORQUE experiment for (c) $\varepsilon = 0.01$ and (d) $\varepsilon = 1$. These curves were calculated according to equations (5) and (9) as a function of the contact time, t_{CP} , where t_{const} was chosen as 5 ms for TORQUE. All the curves were normalized at $t_{CP} = t_{const} = 5$ ms. T_{HF} was kept constant at 0.5 ms, and the relaxation parameters used, $(T_{1\rho}^H, T_{1\rho}^F)$ were (A) (2.5, 100.), B (2.5, 2.5), C (5.0, 5.0) and (D) (100, 2.5), respectively, where the unit is ms. (Reproduced with permission from Ref.⁴⁰)

by $(1/T_{1\rho}^H + 1/T_{1\rho}^F)/2$, not by $1/T_{1\rho}^H$, when $\varepsilon = 1$ and $1/T_{1\rho}^F$ is not negligibly small. The curves A, C, and D actually involve the same value of $(1/T_{1\rho}^H + 1/T_{1\rho}^F)/2$. Consequently, a term involving $1/T_{1\rho}^F$ has to be explicitly incorporated into the analysis of CP dynamics between abundant nuclei. The high natural abundance of ^{19}F often makes $T_{1\rho}^F$ of the same order as $T_{1\rho}^H$. In addition, the heat capacity of the ^{19}F spin bath can be comparable to that of the ^1H spin bath when ε is close to 1. Figure 5(b) clearly indicates that CP curves can not discriminate between the three cases of $T_{1\rho}^H \ll T_{1\rho}^F$, $T_{1\rho}^H = T_{1\rho}^F$, and $T_{1\rho}^H \gg T_{1\rho}^F$. This is one of the major reasons that the conventional method can not be applied to analysis of $^1\text{H} \rightarrow ^{19}\text{F}$ CP dynamics.

Furthermore, equation (5) can be approximated by the following

$$\left[\frac{\beta_F(t)}{\beta_{H0}} \right]_{CP} = A \left[-\exp\left(-\frac{t_{CP}}{T_{HF}^*}\right) + \exp\left(-\frac{t_{CP}}{T_{1\rho}^*}\right) \right] \quad (10)$$

where A is a constant, and T_{HF}^* and $T_{1\rho}^*$ are effective time constants for the increase and decay of β_F . This indicates that any kind of CP curve for a homogeneous system can be well described by these two constants using the conventional expression. It is well-known that T_{HF}^* and $T_{1\rho}^*$ are analogous to T_{HF} and $T_{1\rho}^H$, respectively, when the following conditions are fulfilled: (1) F is a rare spin, (2) T_{HF} is considerably shorter than $T_{1\rho}^H$, and (3) $T_{1\rho}^F$ is considerably longer than $T_{1\rho}^H$. We will refer to this extreme situation ($\varepsilon \ll 1$ and $T_{HF} \ll T_{1\rho}^H \ll T_{1\rho}^F$) as the ideal CP condition. However, when ε is not negligibly small and $T_{1\rho}^F$ is comparable to $T_{1\rho}^H$ (as is frequently true for $^1\text{H} \rightarrow ^{19}\text{F}$ CP), no simple relationship is expected between the effective parameters (T_{HF}^* , $T_{1\rho}^*$) and the true parameters for CP dynamics, T_{HF} , $T_{1\rho}^H$, and $T_{1\rho}^F$.

Figure 5(c) shows the TORQUE curves calculated for $\varepsilon = 0.01$. The decay of β_F is effectively suppressed in all the cases, indicating that it is mainly caused by $T_{1\rho}^H$. The shape of the curves is insensitive to the magnitude of $T_{1\rho}^F$. On the other

hand, the TORQUE curves calculated for $\varepsilon = 1$ (Figure 5d) show significantly different behavior from those in Figure 5(c). The decay of β_F can be suppressed only in the cases when $T_{1\rho}^H = T_{1\rho}^F$ (B and C). Otherwise, the slope at $t_{CP} = t_{const}$ is positive for $T_{1\rho}^H \ll T_{1\rho}^F$ (A) and negative for $T_{1\rho}^H \gg T_{1\rho}^F$ (D). This relationship can be mathematically verified.⁴⁰ Although the TORQUE sequence does not quench the relaxation process with $T_{1\rho}^H$ when ε is not negligibly small, the sign of the slope should be generally helpful in analyzing CP dynamics between abundant nuclei.

The contact-time dependence of β_H can also be obtained by solving equation (1) under the same initial conditions, giving:

$$\left[\frac{\beta_H(t)}{\beta_{H0}} \right]_{CP} = \frac{1}{a_+ - a_-} \left[- \left(1 + \frac{T_{HF}}{T_{1\rho}^F} - a_+ \right) \exp \left(- \frac{a_+}{T_{HF}} t_{CP} \right) + \left(1 + \frac{T_{HF}}{T_{1\rho}^F} - a_- \right) \exp \left(- \frac{a_-}{T_{HF}} t_{CP} \right) \right] \quad (11)$$

This corresponds to the t_{CP} dependence of the residual H magnetization during the $H \rightarrow F$ CP experiment (which we will refer to as a CP-drain curve).³⁹ Equation (11) indicates that the residual proton magnetization decays with the same time constants of $-\frac{a_+}{T_{HF}}$ and $-\frac{a_-}{T_{HF}}$ as for the increase in F magnetization expressed by equation (5). The first of these time constants relates to the decrease in H magnetization caused by the polarization transfer to F spins, and the second time constant expresses the decrease caused by the relaxation to the lattice. Accordingly, at the ideal CP condition, the rates of the former and the latter processes are equal to $1/T_{HF}$ and $1/T_{1\rho}^H$.

When T_{HF} is much smaller than $T_{1\rho}^H$ and $T_{1\rho}^F$, the coefficient of the second term in equation (11) is expressed as

$$\frac{1}{a_+ - a_-} \left(1 + \frac{T_{HF}}{T_{1\rho}^F} - a_- \right) = \frac{1}{1 + \varepsilon} \quad (12)$$

This indicates that, when the spin-lattice relaxation is very slow, the proportion of the residual magnetization in the H spin bath to the transferred magnetization to the F spin bath after CP is $1/(1 + \varepsilon)$. In particular, this term becomes unity at the ideal CP condition.

Equation (11) can also be expressed in terms of effective values in the same way as equation (10). The corresponding equation for fitting CP-drain curves is

$$\left[\frac{\beta_H(t)}{\beta_{H0}} \right]_{CP} = (1 - B) \cdot \exp \left(- \frac{t_{CP}}{T_{HF}^*} \right) + B \cdot \exp \left(- \frac{t_{CP}}{T_{1\rho}^*} \right) \quad (13)$$

It should be noted that the magnitude of the H magnetization can be normalized at $t_{CP} = 0$, which is a distinguishing feature of CP-drain curves. One may deduce additional information from the intensity of CP-drain curves, while only the shape of curves (slopes) can be examined for CP-curves. At the ideal CP condition, the decay of H magnetization is principally characterized by $-1/T_{1\rho}^H$ because $B = 1/(1 + \varepsilon)$ is unity and $T_{1\rho}^* = T_{1\rho}^H$. When B takes a value between 0 and 1, this value is related to the proportion of the H magnetization that does not transfer to the F spin bath during $H \rightarrow F$ CP. As described above, when T_{HF} is much smaller than $T_{1\rho}^H$ and $T_{1\rho}^F$, B can be determined as the intercept of the slower decaying part of the CP-drain curve, which represents the relaxation to the lattice (time constant $= -1/T_{1\rho}^*$), to $t_{CP} = 0$, and this value should be equal to $1/(1 + \varepsilon)$.

Furthermore, the comparison between equations (5) and (10) enables one to examine the relationship between T_{HF}^* , T_{HF} , $T_{1\rho}^*$ and $T_{1\rho}^H$ by introducing two parameters, f_1 and f_2 .

$$T_{HF}^* = \frac{T_{HF}}{a_+} = \frac{T_{HF}}{a_0 + \sqrt{a_0^2 - b}} = f_1 \cdot T_{HF} \quad (14)$$

$$T_{1\rho}^* = \frac{T_{HF}}{a_-} = \frac{1}{a_0 - \sqrt{a_0^2 - b}} \frac{T_{HF}}{T_{1\rho}^H} \cdot T_{1\rho}^H = f_2 \cdot T_{1\rho}^H \quad (15)$$

The values of f_1 and f_2 can be calculated as functions of three parameters, namely ε , $T_{HF}/T_{1\rho}^H$ and $T_{HF}/T_{1\rho}^F$. At the ideal CP

Figure 6 Contour maps of the two parameters f_1 (a) and f_2 (b) that were calculated according to equation (14) and equation (15) for $\varepsilon = 0.01$. These two factors are expressed as functions of $T_{HF}/T_{1\rho}^H$ and $T_{HF}/T_{1\rho}^F$. The limiting value of f_1 at $T_{HF}/T_{1\rho}^H \rightarrow 0$ and $T_{HF}/T_{1\rho}^F \rightarrow 0$ is 1.0. (Reproduced with permission from Ref.³⁹)

Figure 7 Contour maps of the two parameters f_1 (a) and f_2 (b) calculated for $\varepsilon = 1$. The limiting value of f_1 at $T_{\text{HF}}/T_{1\rho}^{\text{H}} \rightarrow 0$ and $T_{\text{HF}}/T_{1\rho}^{\text{F}} \rightarrow 0 = 0.5$. (Reproduced with permission from Ref.³⁹)

condition, f_1 and f_2 are unity (see below). Hence, f_1 and f_2 indicate the degree of deviation of the CP dynamics concerned from the ideal CP condition.

Figures 6(a) and 6(b) show the contour maps of f_1 and f_2 calculated using equations (6)–(8) when $\varepsilon = 0.01$, corresponding to the case of chemically dilute fluorines (or to the standard $^1\text{H} \rightarrow ^{13}\text{C}$ situation). These two factors are expressed as functions of $T_{\text{HF}}/T_{1\rho}^{\text{H}}$ and $T_{\text{HF}}/T_{1\rho}^{\text{F}}$. Figure 6(a) indicates that, when $T_{\text{HF}}/T_{1\rho}^{\text{H}}$ and $T_{\text{HF}}/T_{1\rho}^{\text{F}}$ are smaller than 0.1, $T_{1\rho}^*$ and T_{HF}^* are analogous to $T_{1\rho}^{\text{H}}$ and T_{HF} , respectively, within an error of 10%. This condition is commonly fulfilled in semi-crystalline and amorphous polymers at temperatures lower than glass transition temperatures. Moreover, $T_{1\rho}^*$ has a similar value to $T_{1\rho}^{\text{H}}$ in a wide region of the map. These results support the use of the conventional method for the analysis of CP dynamics as long as the conditions described above are fulfilled, so that $T_{1\rho}^*$ and T_{HF}^* can be taken as $T_{1\rho}^{\text{H}}$ and T_{HF} , respectively. On the other hand, Figures 7(a) and 7(b) show the contour maps of f_1 and f_2 calculated when $\varepsilon = 1$, corresponding to many $^1\text{H} \rightarrow ^{19}\text{F}$ CP situations.

These figures exhibit distinctly different features from those in Figure 6. Even when T_{HF} is one hundredth of $T_{1\rho}^{\text{H}}$ and $T_{1\rho}^{\text{F}}$, the effective T_{HF}^* is only half of T_{HF} . This indicates that the effective ('observed') T_{HF}^* is much shorter than the true value of T_{HF} when ε is not negligibly small. By using equation (14), it can be shown that T_{HF}^* is equal to $T_{\text{HF}}/(1 + \varepsilon)$, when T_{HF} is much shorter than $T_{1\rho}^{\text{H}}$ and $T_{1\rho}^{\text{F}}$. This corresponds to the fact that the rates of the initial increase in the CP-curve and the fast decrease in the CP-drain curve are faster than the respective values of T_{HF} , as seen in Figure 6(b). In addition, f_2 is very sensitive to the variation in $T_{\text{HF}}/T_{1\rho}^{\text{H}}$ and $T_{\text{HF}}/T_{1\rho}^{\text{F}}$. This indicates that the $T_{1\rho}^*$ value determined from the slope of the experimental decay in the CP curve might not be similar to $T_{1\rho}^{\text{H}}$. This result can be explained by the decaying slope of the CP curve being principally determined by $(1/T_{1\rho}^{\text{H}} + 1/T_{1\rho}^{\text{F}})/2$, not by $1/T_{1\rho}^{\text{H}}$, when $\varepsilon = 1$, as described

above. This corresponds to the decaying slopes of the CP and CP-drain curves being considerably different from the relevant values of $T_{1\rho}^{\text{H}}$.

The approach described above can be generalized for any number of spin baths.⁴² Typically, at modest MAS rates, a single proton spin bath but several fluorine spin baths will exist. This situation occurs when the proton spectrum is homogeneous whereas the relatively large chemical shift differences for ^{19}F ensure that separate signals are observed when proton-decoupling is employed. Under $^1\text{H} \rightarrow ^{19}\text{F}$ CP conditions, spin exchange between the various ^{19}F spin baths can occur at varying rates (this will include a r.f.-driven CP-like component) (see Figure 8).

Simulations of multiple abundant spin-bath CP are based on a simple extension of the problem of two spin baths. Spins in separate baths, with inverse spin temperatures β_i , β_j etc., may be in contact with each other and with the lattice as seen in Figure 8. Invoking the constraints required by the conservation of energy in the rotation frame and the long-term equilibrium distribution of spin temperatures, the following differential equations can be derived, which are analogous to those in equation (1).

$$\begin{aligned}
 \frac{d}{dt}\beta_A &= \frac{1}{T_{AB}}[\beta_B - \beta_A] + \frac{1}{T_{AC}}[\beta_C - \beta_A] + \cdots + \frac{1}{T_{AN}}[\beta_N - \beta_A] - \frac{1}{T_{1\rho}^A}\beta_A \\
 \frac{d}{dt}\beta_B &= \frac{\varepsilon_{AB}}{T_{AB}}[\beta_A - \beta_B] + \frac{1}{T_{BC}}[\beta_C - \beta_B] + \cdots + \frac{1}{T_{2N}}[\beta_N - \beta_B] - \frac{1}{T_{1\rho}^B}\beta_B \\
 \frac{d}{dt}\beta_C &= \frac{\varepsilon_{AC}}{T_{AC}}[\beta_A - \beta_C] + \frac{\varepsilon_{BC}}{T_{BC}}[\beta_B - \beta_C] + \cdots + \frac{1}{T_{2N}}[\beta_N - \beta_C] - \frac{1}{T_{1\rho}^C}\beta_C \\
 &\vdots \\
 \frac{d}{dt}\beta_N &= \frac{\varepsilon_{AN}}{T_{AN}}[\beta_A - \beta_N] + \frac{\varepsilon_{BN}}{T_{BN}}[\beta_B - \beta_N] + \cdots + \frac{\varepsilon_{N-1N}}{T_{N-1N}}[\beta_{N-1} - \beta_N] - \frac{1}{T_{1\rho}^N}\beta_N
 \end{aligned} \tag{16}$$

In matrix form equation (16) is expressed as $\frac{d}{dt}\mathbf{B} = \mathbf{R} \cdot \mathbf{B}$, where $\mathbf{B} = [\beta_A, \beta_B, \beta_C, \dots, \beta_N]^T$. This system of equations can be solved as $\mathbf{B}(t) = \exp(\mathbf{M}t) \cdot \mathbf{B}(0)$ where $\mathbf{M}$ is the matrix shown in equation (17).

$$\begin{bmatrix}
 -\frac{1}{T_{AB}} - \frac{1}{T_{AC}} - \dots & \frac{1}{T_{AB}} & \frac{1}{T_{AC}} & \dots & \frac{1}{T_{AN}} \\
 -\frac{1}{T_{AN}} - \frac{1}{T_{1\rho}^A} & & & & \\
 \frac{\varepsilon_{AB}}{T_{AB}} & -\frac{\varepsilon_{AB}}{T_{AB}} - \frac{1}{T_{BC}} - \dots & \frac{1}{T_{BC}} & \dots & \frac{1}{T_{BN}} \\
 & -\frac{1}{T_{BN}} - \frac{1}{T_{1\rho}^B} & & & \\
 \frac{\varepsilon_{AC}}{T_{AC}} & \frac{\varepsilon_{BC}}{T_{BC}} & -\frac{\varepsilon_{AC}}{T_{AC}} - \frac{\varepsilon_{BC}}{T_{BC}} - \dots & \dots & \frac{1}{T_{CN}} \\
 & & -\frac{1}{T_{CN}} - \frac{1}{T_{1\rho}^C} & \dots & \\
 \vdots & \vdots & \vdots & \ddots & \vdots \\
 \frac{\varepsilon_{AN}}{T_{AN}} & \frac{\varepsilon_{BN}}{T_{BN}} & \frac{\varepsilon_{CN}}{T_{CN}} & \dots & -\frac{\varepsilon_{AN}}{T_{AN}} - \frac{\varepsilon_{BN}}{T_{BN}} - \dots \\
 & & & & -\frac{\varepsilon_{N-1N}}{T_{N-1N}} - \frac{1}{T_{1\rho}^N}
 \end{bmatrix} \quad (17)$$

Figure 8 Diagrammatic view of cross-polarization dynamics for a system of four spin baths where one of them, A say, is initially produced in a non-equilibrium state by a 90° pulse. Each spin bath is characterized by an inverse spin temperature, β , and a relative population, ε

$\text{Exp}(\mathbf{M})$ can be evaluated as $\mathbf{A}^{-1} \cdot \text{exp}(\mathbf{D}) \cdot \mathbf{A}$ where $\mathbf{D}$ is the matrix of eigenvalues and $\mathbf{A}$ is the matrix of eigenvectors.

A computer program has been written,⁴² using equation (17), to iteratively fit CP curves to yield values of characteristic inter-bath spin-exchange times (T_{HF} and T_{FF}), using separately measured values of $T_{1\rho}^{\text{H}}$ and $T_{1\rho}^{\text{F}}$ as part of the input.

4 FLUOROPOLYMERS

There have been four comprehensive reviews^{1,2,43,44} in the last decade relating to the high-resolution ^{19}F NMR of fluoropolymers containing hydrogen. In 1987, a pioneering work on high-resolution ^{19}F MAS NMR at spin rates between 18

and 22 kHz was reported by Dec et al.¹³ for copolymers of vinylidene fluoride (CF_2CH_2 , VDF) and hexafluoropropylene (CF_3CFCF_2 , HFP) and of VDF and chlorotrifluoroethylene (CF_3CFCl), and for terpolymers of VDF, HFP, and tetrafluoroethylene (CF_2CF_2 , TFE). Structural assignments of chemical shifts in terms of pentad sequences were made on the basis of solution-state NMR. Recently, Isbester et al.⁴⁵ recorded ^{19}F NMR spectra for the same kinds of polymers by simultaneously using MAS rates up to 25 kHz and heating to 250°C . Very high resolution was achieved at the higher temperatures,⁴⁶ and the peaks were assigned by comparison to results from solution-state NMR studies. Detailed monomer compositions of six polymers were quantitatively determined. The authors reported that equivalent resolution was observed for a copolymer if a spectrum acquired at a spin rate of 19 kHz is compared to the corresponding spectrum acquired at 4 kHz and a 50°C higher temperature.

Harris and coworkers^{22,24–27,30,39,40,47,49} have conducted a number of high-resolution ^{19}F NMR studies utilizing MAS, cross polarization (CP), and high-power proton/fluorine decoupling. In particular, several efforts have been devoted to poly(vinylidene fluoride) (PVDF) because of its interesting polymorphism and dielectric properties. The results from ^{19}F -pulsed, ^{19}F wide-line, ^{19}F MAS and $^1\text{H} \rightarrow ^{19}\text{F}$ CPMAS NMR of PVDF, all with high-power proton decoupling, have been reviewed in detail.² Holstein et al.²⁴ have reported that, with ^1H decoupling, PVDF powder obtained from the melt shows, at ambient probe temperature, a major signal (peak I in Figure 9(c)), together with shoulders (on both high-frequency and low-frequency sides, II and III) and a weak doublet at lower frequency (peaks IV and V). The weak doublets were assigned to chain imperfections of *head-to-head* and *tail-to-tail* sequences, and the shoulders arise from crystalline regions.

The authors²⁴ showed that discrimination in favor of the crystalline regions can be obtained by spin-locking the protons prior to CP contact because $T_{1\rho}^{\text{H}}$ is substantially shorter for amorphous chains. On the other hand, discrimination in favor of the amorphous region was achieved by the dipolar dephasing pulse sequence because the hetero-nuclear dipolar interaction is substantially stronger for crystalline chains. Figure 9(b) shows a spectrum of the amorphous (mobile)

Figure 9 188.29 MHz ^{19}F spectra of solid PVDF powder using (a) $^1\text{H} \rightarrow ^{19}\text{F}$ CP and (b) the DIVAM (discrimination induced by variable amplitude minipulses) pulse sequence, both obtained at a spin rate of 13.5 kHz with high-power ^1H decoupling. The DIVAM CP pulse sequence selectively observes the amorphous region. The spectra **c** and **d** show deconvolutions of **a** and **b** respectively, obtained using Lorentzian functions. For a discussion of the peaks I to V, see the text. (Reproduced with permission from Ref.⁴⁹)

domains obtained with an alternative pulse sequence.⁴⁹ This indicates that the imperfections are largely or wholly in the amorphous regions. Scheler et al.²² have applied the two-dimensional (^1H and ^{19}F) wideline separation (WISE) sequence²¹ to PVDF, both with and without ^{19}F -decoupling during the ^1H evolution time. The resulting spectra exemplify the mobility differences between the amorphous and α -crystalline chains. The signals from crystalline and amorphous regions were clearly distinguished in the proton lineshapes and the second moments of the lines. The selection of subspectra from the amorphous and crystalline parts of the polymer by dipolar and $T_{1\rho}$ filters, respectively, strongly supports the assignments.

There are two major crystalline forms, denoted α and β , in PVDF. The chains of the α -form have the tg^+tg^- conformation, whereas those in the β -form have the all-*trans* conformation. Holstein et al.²⁵ have studied samples with partial conversion of the α -form to the β -form (obtained by uniaxial or biaxial drawing) and have shown that the β -form gives a single signal at $\delta_{\text{F}} = -98$ ppm whereas the α -form give two signals at $\delta_{\text{F}} = -82$ ppm (peak II) and -98 ppm (peak III), as described above. The immobile chains in the crystalline regions required the application of proton high-power decoupling to completely remove proton-fluorine interactions. The origin of the chemical shifts can be well understood in terms of the γ -gauche effect. Scheler¹⁵ has shown that magic-angle spinning at 30 kHz or more adequately averages (H,F) as well as (F,F) dipolar interactions for PVDF giving high-resolution ^{19}F spectra. This removes the requirement for high-power proton decoupling. Scheler¹⁵ also

showed that the two-dimensional RFDR technique provides a simple test for the spatial proximity of different types of fluorines and thus enables the domain structure of PVDF to be explored. However, for the RFDR experiment proton decoupling is essential even at the highest spinning speeds because the recoupling pulses also recouple heteronuclear coupling.

Su and Tzou⁴⁸ have also examined the polymorphism of PVDF using fast MAS with spin speeds up to 35 kHz without ^1H decoupling. They were thus able to estimate the proportions of the crystalline region, amorphous region, and defect segments as 41%, 54%, and 5% respectively. The authors also analyzed spinning sideband manifolds in PVDF ^{19}F spectra obtained at very high magnetic fields (752.8 MHz frequency) to yield shielding tensor principal components for the different signals, though they do not seem to have taken into account any effects from (H,F) or (F,F) dipolar interactions on sideband intensities. They show that the two peaks assigned to crystalline regions have different shielding tensors, and that their shielding anisotropies are significantly larger than that of the amorphous peak, as commented earlier by Holstein et al.²⁵ Like Scheler,¹⁵ Su and Tzou⁴⁸ used 2D spin-diffusion experiments to indicate proximity between the fluorine sites giving the crystalline-phase signals, and also between the fluorines in the defect structures and those of the amorphous regions. Ando et al.⁴⁹ have measured ^{19}F spin-lock, $^1\text{H} \rightarrow ^{19}\text{F}$ CP, and $^1\text{H} \rightarrow ^{19}\text{F}$ inversion recovery CP (IRCP) MAS spectra of PVDF to give proton and fluorine relaxation times ($T_{1\rho}^{\text{F}}$, $T_{1\rho}^{\text{H}}$) and effective parameters (T_{HF}^* , $T_{1\rho}^*$) relating to $^1\text{H} \rightarrow ^{19}\text{F}$ CP (Figure 10).

Figure 10 Dependence of the ^{19}F signal intensities for (a) $^1\text{H} \rightarrow ^{19}\text{F}$ CP and (b) $^1\text{H} \rightarrow ^{19}\text{F}$ IRCP experiments on PVDF at short contact times with MAS at 13.5 kHz and for $B_0 = 4.7$ T. The pre-contact time of the IRCP was 0.2 ms, and the signal intensities of peaks II and III are displaced downwards in (b) to avoid overlap of symbols. The dips originating from the dipolar oscillation behavior are indicated by arrows. Reproduced with permission of Ref.⁴⁹

The values of $T_{1\rho}^{\text{F}}$, $T_{1\rho}^{\text{H}}$ and $T_{1\rho}^*$ for peaks II and III in Figure 9 (crystalline region) are larger than those of peaks I, IV, and V (amorphous region), whereas the values of T_{HF}^* for the former pair of peaks are significantly shorter than those of the latter set of peaks. These facts coincide well with the stronger heteronuclear dipolar interactions in the crystalline region of PVDF. Although there is no difference in the spin dynamics between the CP and IRCP experiments, IRCP is superior to the standard CP in observing details of CP processes. The dipolar oscillations in the ^{19}F spectral intensities are clearly observed in the initial stage for IRCP not only for the crystalline peaks, but also for the amorphous peaks (Figure 10b). The first dips observed for peaks II and III are at 0.125 ms, while that for peak I is at 0.425 ms and those for peaks IV and V are around 0.25 ms. The effective average F–H bond distances calculated from these values are 2.2 Å, 3.3 Å, and 2.7 Å, respectively. The longer effective distances in the amorphous peaks are straightforwardly ascribed to molecular motion of the order of several tens of kHz. In addition, the authors⁴⁹ measured the $^{19}\text{F} \rightarrow ^1\text{H}$ CP MAS spectrum of PVDF. The spinning sidebands originate from the residual

dipolar interactions that are not averaged out by MAS at a spin rate of 13.5 kHz. Although the main peak and spinning sidebands can be fitted by single Lorentzian functions, the half-height width (hwh) of the former (900 Hz) is significantly smaller than those of the latter (ca. 3000 Hz). This suggests that the contribution of the amorphous signal is mostly limited to the main peak, while that of the crystalline signal is distributed to both the centreband and sidebands. The $^{19}\text{F} \rightarrow ^1\text{H}$ CP dynamics (especially the effective parameter, T_{FH}^*) and the dipolar oscillation behavior, which is only observed for the sidebands, support this view. This phenomenon coincides well with the fact²⁷ that the spinning sidebands in a ^1H -decoupled ^{19}F MAS spectrum at a spin rate of 12 kHz contribute substantially to the spectra of the crystalline region.

Monti et al.⁴⁷ have investigated ^{19}F MAS and $^1\text{H} \rightarrow ^{19}\text{F}$ CP/MAS NMR spectra of Viton-type fluoroelastomers (Figure 11), which are copolymers of VDF and HFP, and terpolymers containing TFE units also.

The $^1\text{H} \rightarrow ^{19}\text{F}$ CP and TORQUE curves were well fitted by modified conventional equations, and different effective parameters were obtained for five separate peaks, which gave some insight into the CP dynamics between protons and fluorines, although the high abundance of fluorine atoms and efficient $T_{1\rho}^{\text{F}}$ process were not explicitly considered. Ando et al.⁴⁰ also measured $^1\text{H} \rightarrow ^{19}\text{F}$ CP/MAS spectra of a Viton-type fluoroelastomer and reexamined the CP dynamics between ^1H and ^{19}F using the exact solutions of the equations for the spin thermodynamics. Simultaneous fitting of the evolution of magnetization in the standard CP and TORQUE experiments (Figure 12) gave unique sets of the parameters T_{HF} , $T_{1\rho}^{\text{H}}$, and $T_{1\rho}^{\text{F}}$ for the five separate peaks in the ^{19}F spectra.

The values of $T_{1\rho}^{\text{H}}$ and $T_{1\rho}^{\text{F}}$ are consistent with those independently measured by spin-locking experiments. The true values of T_{HF} are significantly larger (by a factor of ca. 4) than the values of T_{HF}^* derived from a simple two-parameter fit of the CP behavior with variable contact time.

Ando et al.³⁹ have also measured (Figure 13) ^{19}F MAS, $^1\text{H} \rightarrow ^{19}\text{F}$ CP, and $^1\text{H} \rightarrow ^{19}\text{F}$ CP-drain MAS spectra for a fluorinated polyimide, 6FDA/ODA. The CP dynamics between ^1H and ^{19}F for the polyimide (Figure 13) were analyzed

Figure 11 188.29 MHz fluorine-19 MAS spectrum of Viton obtained with proton decoupling, together with the assignments of the peaks

Figure 12 Simultaneous fitting of CP and TORQUE curves for CF_2 of VDF and CF of HFP units. Unique sets of three parameters (T_{HF} , $T_{1\rho}^{\text{H}}$, $T_{1\rho}^{\text{F}}$) were determined as shown in the figures. Filled circles and triangles represent the signal intensities obtained from the conventional CP and TORQUE experiments, respectively, and solid and dotted lines represent the fitted curves. (Reproduced with permission from Ref.⁴⁰)

on the basis of the spin-thermodynamics theory described in the former section. The constant for polarization transfer (T_{HF}) was determined by the analysis using the effective CP parameters (T_{HF}^* , $T_{1\rho}^*$) together with independently measured values of $T_{1\rho}^{\text{H}}$ and $T_{1\rho}^{\text{F}}$. The CP-drain experiment, which can measure evolution of residual ^1H magnetization after $^1\text{H} \rightarrow ^{19}\text{F}$ CP, was developed, and the value of ε thus obtained (0.49) was close to that determined from the chemical structure ($N_{\text{F}}/N_{\text{H}} = 0.43$) (Figure 13).

Reinsberg et al.³⁰ have examined ^{19}F MAS, $^1\text{H} \rightarrow ^{19}\text{F}$, and $^1\text{H} \rightarrow ^{13}\text{C}$ CP/MAS spectra of semi-crystalline poly(trifluoroethylene) (PTFE). The ineffectiveness of the selection schemes between crystalline and amorphous regions ($T_{1\rho}$ -filter and dipolar dephasing) indicates that relaxation parameters differ by less than an order of magnitude. The α -relaxation at ca. 50°C was proved by a steep decrease of the $^1\text{H} \rightarrow ^{19}\text{F}$ CP efficiency for the CF_2 fluorines. The dipolar oscillation frequencies in $^1\text{H} \rightarrow ^{13}\text{C}$ CP curves were used to infer the

Figure 13 Contact time dependence of the ^1H signal intensity for the $^1\text{H} \rightarrow ^{19}\text{F}$ CP (circles) and the $^1\text{H} \rightarrow ^{19}\text{F}$ CP-drain (diamonds) experiments at $B_0 = 4.7$ T on the fluorinated polyimide. They show the double-exponential behavior, and the value of ε ($=N_{\text{F}}/N_{\text{H}}$) can be calculated from the intercept of the slowly decaying line of the CP-drain curve to $t_{\text{CP}} = 0$

motion of the polymer chain through effective bond distances, and it was concluded that the localized motion of the main chain is considerably hindered at -30°C .

Ando et al.²⁶ have investigated $^1\text{H} \rightarrow ^{19}\text{F}/^{19}\text{F} \rightarrow ^1\text{H}$ CP/MAS and ^1H fast MAS spectra of semi-crystalline poly(vinylfluoride) (PVF). Significant differences in $T_{1\rho}^{\text{F}}$ and $T_{1\rho}^{\text{H}}$ were observed between the immobile and mobile regions, and the effective time constants, T_{HF}^* and $T_{1\rho}^*$ estimated from the $^1\text{H} \rightarrow ^{19}\text{F}$ CP curves also clarify the difference in the strengths of dipolar interactions. The inverse $^{19}\text{F} \rightarrow ^1\text{H}$ CP-MAS and $^1\text{H} \rightarrow ^{19}\text{F}$ CP-drain MAS experiments also gave complementary information to the $^1\text{H} \rightarrow ^{19}\text{F}$ CP-MAS spectra, although spinning at 35 kHz is necessary to separate the signals between CHF and CH_2 protons in the ^1H spectra. The dipolar oscillation frequency observed for a crystalline peak in the $^1\text{H} \rightarrow ^{19}\text{F}$ CP spectrum correlates well with the H-F distance for a CHF group.

Mabboux and Gleason⁵⁰ have studied electron-beam-irradiated vinylidene fluoride/trifluoroethylene (VDF/TrFE) copolymers using high-speed (up to 25 kHz) high-temperature (up to 170°C) MAS ^{19}F NMR in order to characterize the structure of the polymer. No peaks assigned to crosslinks were resolved, though the crosslinking was implied by linewidth effects. Lau and Gleason^{51,52} have reported ^{19}F MAS NMR measurements of films obtained from pulsed plasma-enhanced chemical vapor deposition from hydrofluorocarbon gases, CHF_2CHF_2 and CH_2F_2 at a spin rate of 25 kHz and analyzed their chemical compositions. Various network sequences, namely three CF_3 (CF_3^*C , CF_3^*CF , CF_3^*CF_2), five CF_2 ($\text{CF}_2\text{CF}_2^*\text{CF}_2$, $\text{CF}_2\text{CF}_2^*\text{CF}_3$, $\text{CF}_2\text{CF}_2^*\text{CHF}_2$, $\text{CF}_2\text{CF}_2\text{CF}_2^*$, $\text{CF}_x\text{CF}_2^*\text{CF}_x$), and three CF (CF^* , CH_2F^* , $\text{CF}^*=\text{C}<$) segments, were identified in the spectra. Fluorine-19 spin-echo NMR measurements with long delay times (6 ms) were used for selective detection of the mobile region with slower transverse relaxation. In addition, the CF_2 peaks suffered significantly

Figure 14 Schematic chemical structure of copoly, which has $x:y = 70:30$. The signals from the three CF_2 groups marked as 'internal' are unresolved, so these fluorines are treated as a single spin-bath

Figure 15 Diagram of the spin baths used for the copoly, with the values for the various rate constants obtained by simultaneously fitting the contact-time curves as shown in Figure 16. The spin-bath populations are also given (in %)

greater intensity loss by spin-echo experiments compared to the CF_3 and CHF peaks, which indicates that the latter groups are relatively more mobile.

The iterative fitting of a multiple spin-bath situation, as described in the previous section, has been applied⁴² to the fluoropolymer shown in Figure 14 (which will be referred to as copoly). This system was treated as a problem involving five spin baths, as shown in Figure 15. The corresponding CP curves, Figure 16, were fitted using a program written in MATLAB. The various CP rate parameters, given in Figure 15 were optimized using the Levenberg-Marquardt non-linear least-squares routine.⁵³ Separately measured $T_{1\rho}$ values were used as constraints. The $^1\text{H} \rightarrow ^{19}\text{F}$ CP rates are indicative of the structure of the fluorocarbon sidechain.

5 FLUORINATED ORGANIC COMPOUNDS

In addition to their practical importance, small organic molecules play an essential role as model systems to study NMR effects. Some examples of such use as models will be discussed below. Their major advantage is that they usually exhibit a high degree of crystallinity. On the other hand,

the absence of significant motional averaging requires the application of all relevant line-narrowing techniques to obtain high-resolution solid-state spectra.

The large chemical shift range of ^{19}F results in a strong dependence of the Larmor frequency on the chemical environment. This implies the presence of information about both the chemical structure and the spatial arrangement. Therefore, fluorine chemical shifts appear to provide an appropriate tool to study polymorphism. It is also possible to use two-dimensional correlation techniques for the assignment of the signals of the respective forms.

The first applications of $^{19}\text{F}\{-^1\text{H}\}$ MAS NMR to monofluorinated organic solids were carried out by Hagaman.⁷ However, this author reported no ^{19}F high-resolution spectra, but only ^{19}F transverse relaxation times for several different chemical types, including the dependence of T_2 on proton decoupling power. Contemporaneously and independently, Harris and co-workers^{8,54} studied three solid fluorinated steroids by $^{19}\text{F}\{-^1\text{H}\}$ MAS NMR, including a system containing three non-equivalent fluorines. They showed that the technique offered considerable advantages over $^{13}\text{C}\{-^1\text{H}\}$ NMR for detection and study of polymorphism. The preliminary communication⁸ was followed by a full article¹⁰ discussing the methodology of the $^{19}\text{F}\{-^1\text{H}\}$ experiment, using the fluorinated steroids as examples, and discussing, inter alia, questions of decoupling efficiency, cross-polarization, ^{19}F shielding tensors, spin-lattice relaxation, spin diffusion, dipolar dephasing and rotational resonance. A further article by the same group reported results for a wider range of fluoro-organic systems.⁹

Vierkötter¹¹ recognized, for the first time, the significant influence (at low or moderate static magnetic fields) of the Bloch-Siegert effect on $^{19}\text{F}\{-^1\text{H}\}$ spectra of solids (not generally detectable for other solid-state experiments such as $^{13}\text{C}\{-^1\text{H}\}$). She showed that significant line-broadening of ^{19}F peaks arises from this effect if the sample is not confined to a small volume, because of inhomogeneities in B_1 .

Further facets of solid-state $^{19}\text{F}\{-^1\text{H}\}$ NMR have been illustrated using urea or thiourea inclusion compounds containing fluoro-organic guests.^{55–59} Thus, the rate of ring inversion of fluorocyclohexane was studied^{55,56,58} by bandshape-fitting, selective polarization inversion, EXSY spectra and $T_{1\rho}$ measurements over a range of temperatures (Figure 17), yielding the thermodynamic parameters for the barrier.

Linear difluoroalkanes in urea inclusion compounds are disordered in the guest arrangements and $^{19}\text{F}\{-^1\text{H}\}$ NMR proves^{56,57} to be a powerful technique to measure average intermolecular (F,F) distances because ideal isolated two-spin systems are involved.^{56,57} Static MREV-8 and CPMG experiments yield separate information on dipolar coupling and shielding anisotropy, enabling the simple static pattern to be successfully simulated. The resulting data were used to discuss the distribution of end-group conformations in these systems, taking into account rapid molecular motion about the tunnel axis. MELODRAMA experiments gave^{56,59} similar information about dipolar coupling constants for difluoroalkane-urea inclusion compounds.

In the MAS spectrum of 5-fluoro-2-trifluorobenzoic acid (Scheme 1) the signals of the CF and CF_3 fluorines are clearly distinguishable.³⁵ The existence of two different molecules in the asymmetric unit is shown by the appearance of two sets of lines for each of the CF and CF_3 groups, as depicted in

Figure 16 Fitted contact-time $^1\text{H} \rightarrow ^{19}\text{F}$ CP curves for the four ^{19}F spin-baths of copoly, using the theory discussed in the text. (Reproduced from Ref.⁴² by permission of the PCCP Owners Societies)

Figure 17 (a) Simulated and (b) experimental 188.29 MHz ^{19}F NMR spectra of fluorocyclohexane in its solid thiourea inclusion compound recorded at (from bottom to top) 177, 217, 237, 247, 258, 268, 278 and 300 K, with the average ring-inversion rate constants given in ms^{-1} down the right-hand side. The rate constants for 177 and 217 K were obtained using the SPI experiment. (Reproduced with permission from Ref.⁵⁸)

Scheme 1

Figure 18 Fluorine-19 MAS NMR spectrum of 5-fluoro-2-(trifluoromethyl)benzoic acid acquired at a Larmor frequency of 282 MHz and a sample spinning frequency of 32 kHz

Figure 18. A possibility to assign the pairs of signals originating from the respective forms is by spin-exchange based on RFDR (radio-frequency driven recoupling).⁶⁰ This experiment probes spatial proximity by the distance-dependence of the direct dipolar coupling. Cross-peaks off the diagonal, as seen in Figure 19, are an indication of spin exchange during the mixing time, mediated by the direct dipolar coupling and thus spatial proximity. Normally this will link resonances for the same molecule of the asymmetric unit, though sometimes the intermolecular dipolar interactions may be sufficiently strong

Figure 19 Fluorine-19 spin-exchange experiment under radio-frequency driven recoupling for 5-fluoro-2-(trifluoromethyl)benzoic acid, acquired at a Larmor frequency of 282 MHz with a sample spinning frequency of 32 kHz and a mixing time of 0.5 ms

to confuse matters, as is usual for any experiment exploiting the direct dipolar coupling. In this recoupling experiment proton decoupling during the mixing time is essential, because the recoupling would recouple the heteronuclear dipolar coupling as well, and thus suppress the total signal. The same type of information is available using double-quantum NMR⁶¹ as depicted in Figure 20.⁶² In these spectra the chemical shift in the single quantum, directly-detected, dimension is correlated with the double-quantum signal in the indirect dimension, in which the sum of the chemical shifts of the coupled nuclei appears. For double-quantum coherence in a spectrum of spin one-half nuclei, two spins must be coupled. Again, the coupling involved is the distance-dependent direct dipolar effect. The presence of double-quantum coherence is an indication of spatial and spectral proximity. The strength of the dipolar coupling and thus the distance between the coupled nuclei can be determined from a comparison of the spinning sideband pattern in the double-quantum dimension with simulations.

Figure 20 Fluorine-19 double-quantum experiment for 5-fluoro-2-(trifluoromethyl)benzoic acid, acquired at a Larmor frequency of 282 MHz with a sample spinning frequency of 32 kHz using back-to-back pulses with an excitation time of 15 μ s. The extra lines in the expansion indicate the link between the CF and CF₃ signals

Figure 21 Fluorine-19 longitudinal relaxation times of the CF and CF₃ signals for 5-fluoro-2-(trifluoromethyl)benzoic acid as a function of the sample spinning frequency, obtained at a Larmor frequency of 282 MHz

Miyoshi et al. recently investigated³⁴ the dependence on MAS rate of T_1 in partially fluorinated derivatives of benzoic acid. In these systems, the fast rotation of a trifluoromethyl group provides an efficient relaxation sink for ¹⁹F. At moderate sample spinning rates, there is sufficient overlap of the signals from the trifluoromethyl group and the single fluorine spin on the benzene ring to facilitate spin diffusion and thus fast T_1 relaxation of the isolated fluorine. At higher spinning speeds (Figure 21), there is considerable averaging of both the homonuclear and the heteronuclear dipolar coupling to achieve well-separated lines. This means spin flip-flops are no longer energy-conserving, and therefore spin diffusion is efficiently quenched by MAS. This results in a substantially longer T_1 for the isolated fluorine, which can be as large as 20 s. Although no proton decoupling was applied, it is understood that both homonuclear and heteronuclear coupling influence fluorine spin-diffusion. In most perfluorinated systems (such as fluoropolymers), which have a higher fluorine density, the same mono-exponential T_1 has been observed⁶³ for all resolved sites, even under high-speed MAS. This fact is attributed to spin-diffusion, which is rapid on the time scale of T_1 . The same group of compounds has been used³⁴ to test and calibrate internuclear distance measurements using Lee–Goldburg cross-polarization between ¹H and ¹⁹F. The results nicely correspond to the distances determined in molecular simulations.

Another example for monitoring fluorine spin diffusion is provided by spin-exchange in a partially fluorinated steroid (Scheme 2). Spin diffusion has been monitored^{9,10} using spin-exchange spectroscopy based on an EXSY experiment (Figure 22). The rate of spin diffusion between protons is governed by the distance-dependent dipolar coupling only. Spin-diffusion between fluorine nuclei is also determined by the dipolar coupling. However, it can in addition be influenced by the spectral separation. In that case the elementary step in spin diffusion, the flip-flop between two coupled spins is no longer energy conserving. This has been investigated

at moderate sample spinning rates with variations in the mixing time. Such moderate MAS rates, in conjunction with heteronuclear decoupling, provide sufficient line narrowing for the detection of highly resolved spectra. The heteronuclear coupling in this system is still significant at these spinning speeds. Therefore it is possible to effectively manipulate the dipolar coupling by RF pulses, e.g., during the mixing time, so as to investigate the various factors influencing fluorine spin diffusion. When no radio-frequency pulses are applied during mixing (Figure 22a), the spin-exchange rate reflects the spatial proximity of the fluorine nuclei in the molecule. If, however, the proton–fluorine dipolar coupling is suppressed during the EXSY mixing time, no exchange cross-peaks are visible between the CF and the CFH or the CFH₂ fluorine signals (Figure 22b) because suppression of the heteronuclear coupling leads to line narrowing, giving well-resolved, isolated lines in the spectrum. The spin-exchange process is no longer energy conserving and so is hindered. The opposite is true when the chemical shift difference is refocused and the line narrowing by MAS is stopped by rotor-synchronized π pulses during the mixing time (radio-frequency driven recoupling, RFDR). In such experiments (Figure 22c) the exchange rates are determined by the dipolar coupling strength and thus the internuclear distance only. In the case of RFDR, the exchange rate reflects the internuclear distance only when the chemical shift difference in the spectrum is refocused. Spin exchange is nearly suppressed when heteronuclear decoupling is applied. In the fully coupled spectra the exchange rate is influenced by the partial separation of the lines.

Scheme 2

Scheme 3

The cross-polarization and relaxation behavior has been investigated^{9,64} in a semiperfluorinated derivative of adamantane (Scheme 3). This molecule contains four identical sidechains

Figure 22 Two-dimensional 188.29 MHz ^{19}F CPMAS spin-exchange spectra of the fluorosteroid (Scheme 2): (a) without proton decoupling during the mixing time; (b) with proton decoupling during the mixing time; and (c) with RFDR during the mixing time. In all three cases the dwell time in both dimensions was 50 μs , the mixing time 5 ms, spinning rate 10 kHz, recycle delay 2 s, $\pi/2$ pulse duration 3 μs , contact time 2 ms, 32 transients per t_1 point and 128 slices in t_1

containing a CF_2 , a CFH and a CF_3 group each. Different experimental methods for probing the dipolar coupling have been applied. By application of a variant of the DIP-SHIFT experiment,⁶⁵ the heteronuclear dipolar coupling has been correlated with the fluorine chemical shift. Complementary information is obtained from a WISE (wideline separation experiment), where proton wideline information is correlated with the chemical shift of the neighboring fluorine nuclei. Both experiments can be utilized to probe local dynamics, which, via fluorine chemical shifts, can be attributed to chemical substructures. One-dimensional versions of the experiments, on the other hand, can be used as discriminating steps.

Brouwer et al.⁶⁶ have examined the supramolecular inclusion compound *p-tert*-butylcalix[4]arene-fluorobenzene, using $^1\text{H} \rightarrow ^{19}\text{F}$ cross-polarization spectra to show that there must be considerable mobility of the guest fluorobenzene molecule in the host. Spectra of the static complex showed axially symmetric powder patterns with shielding anisotropy $\Delta\sigma = -42$ ppm, whereas solid fluorobenzene has an asymmetric shielding tensor⁶⁷ with $\Delta\sigma = -87$ ppm. The results⁶⁶ for the calixarene host-guest system are consistent with disorder in the crystal structure. Brouwer, Challoner and Harris⁶⁸ have studied a second *p-tert*-butylcalix[4]arene inclusion compound, with α, α, α -trifluorotoluene as a guest. The static $^{19}\text{F}-\{^1\text{H}\}$ spectra were analyzed (Figure 23) in terms of interplay between shielding anisotropy and F,F dipolar coupling to yield the 3 principal components of the shielding tensor and the F,F distances within the CF_3 group. Both shielding and dipolar tensors are strongly averaged by internal rotation about the C- CF_3 bond. The authors also studied the effect of magic-angle and off-angle spinning. The ^{19}F signal is narrow and very sensitive to the exact angle of the spinning axis. It is therefore proposed⁶⁸ that the compound be used to set the magic angle for ^{19}F spectra when proton decoupling is feasible.

Chisholm et al.⁶⁹ examined the $^{19}\text{F}-\{^1\text{H}\}$ MAS spectra of two monofluorinated pigment compounds and showed that in each case there is only one molecule in the asymmetric unit. Campbell et al.⁷⁰ examined two polymorphs of (3*S-trans*)-1-[3,4-dihydro-2,2-dimethyl-6-(pentafluoroethyl)-2*H*-1-benzo-pyran-4-yl]piperidin-2-one but found, somewhat unusually, that the $^1\text{H} \rightarrow ^{19}\text{F}$ CP spectra did not distinguish very clearly between the forms, even though one (only) of them had more than one molecule in the crystallographic asymmetric unit. The ^{13}C spectra proved to be significantly more useful than the ^{19}F spectra.

Shapiro et al.⁷¹ have shown that ^{19}F MAS NMR without proton decoupling gives high-resolution spectra for studying organic solid-phase reaction processes occurring on resin supports, using solvent-swelling (with benzene- d_6) to further decrease the linewidths. Specifically, they studied the reaction of 4-fluoro-3-nitrobenzamide, bonded to a polystyrene resin, with reagents causing an $\text{S}_{\text{N}}\text{Ar}$ displacement of the fluorine atom. The technique is complementary to gel-phase NMR and has the advantage of requiring less accumulation time. Grage et al.⁷² applied a CPMG sequence to obtain pure dipolar spectra of flufenamic acid in a membrane (DMPC; 1,2-dimyristoyl-sn-glycero-3-phosphocholine) and, earlier,⁷³ diflucortolon-21-valerate in a fluorine-19-labelled DMPC; [1-myristoyl-2-(4,4-difluoro-

Figure 23 Experimental (a) and simulated (b) 188.297 MHz $^1\text{H} \rightarrow ^{19}\text{F}\{^1\text{H}\}$ static NMR spectra of the *p*-*tert*-butylcalix[4]arene- α, α, α -trifluorotoluene inclusion compound. The three spectral components are depicted in (c). (Reproduced with permission from Ref.⁶⁸)

myristoyl)-sn-glycero-3-phosphocholine (DMPC- F_2]. An investigation of the orientation dependence of the dipolar coupling strength in oriented membranes yields an order parameter. However, the axial rotation of the lipid molecules, which scales the dipolar couplings, has to be taken into account. With a two-dimensional version of the CPMG experiment, in which for each datapoint a full FID has been acquired, fluorine chemical shift resolution has been achieved under proton decoupling. A further report⁷⁴ on flufenamic acid in DMPC (but with the membrane named as dimyristoylphosphatidylcholine) was published by the same group later. In all three papers a range of NMR experiments (including Hahn echoes, CPMG pulse trains, and single-pulse excitation) was used, on static samples.

6 FLUORINATED ORGANOMETALLIC AND METAL COORDINATION COMPOUNDS

Surprisingly little work has been carried out in this area. Harris and co-workers^{9,75} have used $^{19}\text{F}\{^1\text{H}\}$ MAS NMR to study some organotin fluorides, R_3SnF . Spinning sideband analysis was carried out both on the main signals (arising from molecules containing spin-zero tin isotopes) and on the ' $^{117/119}\text{Sn}$ satellites' (Figure 24). Together with similar measurements on the $^{119}\text{Sn}\{^1\text{H}\}$ spectra, the results enabled the authors to estimate the anisotropies in $^1J_{\text{SnF}}$, though with very large potential errors. In the case of Mes_3SnF (where Mes = mesityl) there are two molecules (with tetracoordinated

Figure 24 188.29 MHz fluorine-19 MAS spectrum of tri-*isobutyltin* fluoride, with the spinning sideband manifolds of the two 'tin satellite' resonances indicated separately. Experimental conditions: $\pi/2$ pulse duration 3.95 μs , spinning rate 2.7 kHz, 128 transients and 5 s recycle delay

tin) in the asymmetric unit and two-dimensional ^{119}Sn , ^{19}F HETCOR spectra enabled the ^{119}Sn and ^{19}F signals to be linked. The experiment was carried out with proton decoupling on both channels. The compound $^n\text{Bu}_3\text{SnF}$, on the other hand, contains pentacoordinate tin (involving Sn-F-Sn bridges), and the ^{19}F shielding anisotropy is substantially larger than for Mes_3SnF .

7 FLUORINATED INORGANIC COMPOUNDS

$^1\text{H} \rightarrow ^{19}\text{F}$ cross-polarization and direct-polarization MAS spectra (along with ^{13}C and ^{31}P) have been obtained⁷⁶ for a solid chlorophosphane with aryl groups containing CF_3 substituents. Four signals were resolved throughout the temperature range -120°C to $+50^\circ\text{C}$ showing that local symmetry for the 2,6- $(\text{CF}_3)_2\text{C}_6\text{H}_3$ aromatic ring is lacking and that internal rotation about the relevant P-C bond is slow (which is not the situation in solution above ambient probe temperature). In contrast, the $^{19}\text{F}\{^1\text{H}\}$ solid-state spectrum of a compound containing the 2,6- $(\text{CF}_3)_2\text{C}_6\text{H}_3\text{PCl}_2$ group as a ligand bonded to platinum shows⁷⁷ a single centreband signal at ambient temperature but a marked change to a more complex spectrum at low temperature. This suggests the slowing of a motional process (either rotation about the C-P bond or about the C- CF_3 bonds) as the temperature is lowered.

Fluorinated diazadiphosphetidines have been studied⁷⁸ by variable-temperature $^{19}\text{F}\{^1\text{H}\}$ direct-polarization spectroscopy. At room temperature the fluorines in $(\text{F}_3\text{PNPh})_2$ are all equivalent because of the existence of a rapid pseudorotation process. However, it was shown that at -106°C this motion becomes slow on the NMR timescale.

8 CONCLUDING REMARKS

It is now clear that ^{19}F NMR has considerable potential for the study of molecular-level mobility and structure of solids across a wide range of chemistry. This is true for heterogeneous systems such as fluoropolymers, as well as for crystalline molecular and framework compounds, including biochemical situations. The considerable benefits from the

high natural abundance, strong magnetic dipole moment and substantial range of isotropic chemical shifts can now be routinely utilized because the technical problems of obtaining high-resolution ^{19}F spectra of excellent quality have now been overcome.

1 INTRODUCTION

1.1 Properties of Fluorine-19

Aside from carbon and hydrogen, fluorine-19 is possibly the most-studied nucleus. The reasons for this include both the properties of the nucleus and the practical importance of molecules containing this element. The nucleus ^{19}F has the advantage of 100% natural abundance and a high magnetogyric ratio, about 0.94 times that of ^1H . The chemical shift range is 20 or more times that of hydrogen, so that resonances of different fluorine nuclei are usually well separated. Furthermore, spectral positions are sensitive to the environments of fluorine atoms. The nuclear spin quantum number is $\frac{1}{2}$, and thus relaxation times are sufficiently long that spin–spin splittings may be resolved. Long-range spin–spin coupling constants have substantial magnitude; this has the advantage of providing extensive connectivity information but, for highly fluorinated molecules, it tends to create large spin systems and make resonances very complex and non-first-order.

Fluorinated molecules have achieved industrial prominence in the production of polymers, as surface active and lubricating materials, as refrigerants, and as anesthetics and drugs. Fluorine is particularly useful as a tracer in biological systems, as there is essentially no natural background, and it is often possible to substitute a single fluorine atom for a hydrogen atom without materially changing the properties of a molecule such as a protein.

Observation of ^{19}F in high-field spectrometers may present some problems, and care is required in selecting appropriate instrumentation. At a field of 11.75 T, corresponding to 500 MHz frequency for protons, the full spectral range for ^{19}F approaches 0.5 MHz. This requires appropriate high speeds for the analog-to-digital converter and wide bandwidths for the amplifiers, as well as large data arrays to afford good spectral resolution for narrow lines. Furthermore, uniform excitation over the whole spectrum requires quite short pulses from the transmitter.

1.2 Reviews and Compilations of Data

A small paperback volume by E. F. Mooney presents an introduction to ^{19}F NMR spectroscopy.¹ It includes a variety of typical spectra, as well as some representative NMR parameters for organic molecules, and it gives the reader an excellent feel for the field. Two full volumes have been devoted to compilations of chemical shifts,^{2,3} one is devoted almost entirely to discussions and tables of spin–spin coupling constants,⁴ and a database for C_xF_y compounds has been described.⁵ A number of reviews covering publications on ^{19}F NMR over specific periods of 1 or 2 years have been included in the *Annual Reports on NMR Spectroscopy*.^{6–12}

2 CHEMICAL SHIFTS

The shielding of fluorine nuclei varies quite widely, as illustrated in Table 1 for the range from XeF_6 at low fields to CH_3F at high fields. Several specific structure types will be discussed later. Compared with the situation for hydrogen, the effects of anisotropic magnetic fields, such as those generated by ring currents, are relatively much less important for fluorine, and the nature of the bonding of the atom has a much greater influence. The presence of unshared electron pairs leads to the existence of excited molecular states at relatively low energies, and these are mixed into the ground state as the result of a perturbation by the magnetic field of a spectrometer, producing an unshielding or ‘paramagnetic’ effect.

Table 1 Representative ^{19}F Chemical Shifts (in ppm to High Frequency of CFCl_3)

XeF_6	550	CFBr_3	7
F_2	430	CF_2Cl_2	–8
ReF_7	345	CF_3CH_3	–62
$\text{ClF}_{5,\text{eq.}}$	412	SiF_6^{2-}	–127
$\text{ClF}_{5,\text{ax.}}$	247	BF_3	–131
WF_6	166	$\text{CF}_2=\text{CF}_2$	–135
$\text{C}_6\text{H}_5\text{SO}_2\text{F}$	66	CH_3F	–272

2.1 References for Chemical Shift Measurements

Many early reports of ^{19}F shifts were based on the use of trifluoroacetic acid as an external reference. Because this is a hazardous and reactive material and because values based upon any external reference suffer from errors related to the magnetic susceptibility and geometry of the sample, it has been replaced by the internal reference fluorotrichloromethane, assigned a shift of zero. Under poor spectrometer resolution, the spectrum of this material has only a single peak, but in an instrument with good resolution this is resolved into four lines, corresponding in order, from low frequency to high frequency, to the presence of three, two, one, or no ^{37}Cl nuclei in the molecule. Thus a different result is obtained if the position of one of the individual lines is taken as reference rather than the center of gravity of the overall pattern. However, effects of medium and temperature on shifts are so large for fluorine that they are likely to lead to greater uncertainties than does the small isotope effect in the reference material.

Table 2 Chemical Shifts of Reference Compounds (in ppm to High Frequency of CFCl_3)

CFCl_3	0
$\text{CFCl}_2\text{CF}_2\text{Cl}$	-68.05
$\text{CFCl}_2\text{CF}_2\text{Cl}$	-72.2
$\text{CF}_3\text{CO}_2\text{H}$	-76.6
C_4F_8	-135.2
C_6F_6	-163

Since the resonance of CFCl_3 is well removed from those of most fluoroorganic molecules, and since many of these molecules require $\text{CF}_2\text{ClCFCl}_2$ in order to dissolve, it is often convenient to use one of the multiplets of this material as a reference for the sample peaks. The shift values for these two resonances compared with CFCl_3 , along with the shifts of a few other materials which have sometimes been used as references, are given in Table 2.

By general agreement, the direction of the chemical shift is taken as positive in the direction of higher *resonance frequency* or lower magnetic field. This requires that the great majority of shift values for ^{19}F be negative with respect to CFCl_3 . It is appropriate in discussing factors affecting *nuclear shielding* to follow the opposite convention: the greater the degree of shielding, the further to high field or *lower frequency* is the resonance.

2.2 Shifts of Fluorines Attached to Carbon

Some generalizations may be made about the ranges of shifts to be found in various environments in highly fluorinated organic molecules. First, we consider the effects of halogens or oxygen, along with other fluorine atoms in aliphatic molecules. In specifying the group in which the fluorine is found, the letter X will be used to represent either another fluorine atom, or an atom of chlorine, bromine, or oxygen. Thus $-\text{CFX}_2$ might be $-\text{CF}_3$, $-\text{CF}_2\text{Br}$, $-\text{CFCl}_2$, $-\text{CF}_2\text{O}-$, and so on, and $-\text{CFX}-$ might be $-\text{CFCl}-$ or $-\text{CFBr}-$.

The fluorine resonance in CF_3 in a saturated molecule appears at -75 to -82 ppm with respect to CFCl_3 and in other $-\text{CFX}_2$ units at -65 to -80 ppm. If the shift in $-\text{CF}_2\text{Cl}$ is compared with that in $-\text{CF}_3$, it is found that this chlorine substitution produces a high-frequency (*downfield*) shift or unshielding of about 10 ppm. However, the second substitution of a chlorine for a fluorine atom, giving $-\text{CFCl}_2$, has the opposite effect, so that the resonance is now more shielded than, and about 5 ppm upfield from, that of $-\text{CF}_2\text{Cl}$. The shifts of CF_3 attached to oxygen or to an alkenic carbon are in the region of -50 to -60 ppm.

The shifts of the fluorine in a $-\text{CFX}$ group in a saturated molecule are observed at about -120 to -130 ppm, and here, in contrast to the $-\text{CFX}_2$ case, substitution of one fluorine by a chlorine, forming a CFCl group, causes an increased shielding of about 6-8 ppm. In a straight-chain fluorocarbon unit, the CF_2 group next to the terminating CF_3 can be identified because it is at -127 ppm, rather than at the -122 ppm characteristic of CF_2 fluorines flanked by other CF_2 groups.

The effect on nearby fluorine atoms of substitution of a chlorine for a fluorine atom in a highly fluorinated straight chain is an unshielding of about 6 ppm if the chlorine is on the adjoining carbon, and about 3 ppm if the chlorine is on a

carbon atom one removed from the fluorine being observed. Calculations have been made to predict and correlate shifts in a wide variety of highly halogenated molecules.^{13,14}

Shifts to lower field or to higher frequency, as for chlorine substitution, are produced by substitution of bromine on a vicinal carbon. The effect of chlorine or bromine has been attributed to a van der Waals interaction between the halogen and fluorine and termed 'repulsive unshielding'. Similar unshielding is caused by crowding of a fluorine atom by a methyl group.¹⁵

Substitution of hydrogen for fluorine in either $-\text{CF}_2$ or $-\text{CF}_2\text{X}$ increases the shielding of the remaining fluorine. A tertiary fluorine atom is usually found at a relatively high field (about -160 to -180 ppm).

A carbonyl group in a perfluorinated chain typically causes unshielding of 2-5 ppm for fluorine atoms attached to the α carbon atoms, and an amine nitrogen in the chain produces an unshielding effect for α fluorine atoms of 5-10 ppm. A fluorine atom attached directly to a carbonyl carbon, in an acid fluoride unit, resonates at +30 to +50 ppm.

Fluorine atoms attached to an alkenic carbon atom appear anywhere in the range -50 to -220 ppm. In aromatic molecules, a fluorine substituent resonates anywhere from -100 to -180 ppm. The chemical shift difference produced by a second substituent in the *meta* or *para* position on a benzene ring correlates well with Hammett substituent parameters. If the substituent is *ortho* to the fluorine atom, substantial deviations appear, caused either by van der Waals forces or by electric field effects, and are experienced at the relatively short distances between the fluorine and the *ortho* substituent.

2.3 Shifts of Fluorine Atoms Attached to Other Nonmetals

Many fluorine atoms attached to nitrogen, oxygen, or sulfur resonate to low field or high frequency of CFCl_3 and thus are assigned positive shift values. In $\text{F}-\text{O}-\text{C}$ units, the shift is often in the range 144-155 ppm,¹⁶ but may vary as much as ± 100 ppm from this region. In an NF_2 group, the shift is 15-20 ppm if the group is attached to CF_2 , 20-30 ppm if attached to saturated $-\text{CF}-$, 50-60 ppm if attached to CH_2 in an aliphatic chain, and 30-45 ppm if attached to CH in an aliphatic chain. In an $-\text{NF}-$ group the shifts are -80 to -120. In $=\text{NF}$, there is a very wide variation with the attached structure, from +55 to -67 ppm.¹⁷

Several compounds illustrate these shifts as well as shifts of fluorine attached to sulfur. In $\text{SF}_5\text{SO}_3\text{F}$, the fluorine atom attached to oxygen is at 46 ppm, the equatorial and axial fluorine atoms on sulfur are at 73 and 57 ppm, respectively. In FSO_3F , the OF is at 249 ppm and the SF is at 37 ppm.¹⁸ In OF_2 , the shift is 250 ppm, also far downfield. In SF_5NF_2 , the NF_2 fluorine atoms are at 78 ppm, the equatorial fluorine atoms on sulfur are at 38 ppm, and the axial fluorine atom is at 50 ppm; with nitrogen attached to the sulfur, the equatorial-axial order is reversed from that when the octahedral sulfur atom is attached to another sulfur or to oxygen.

2.4 Isotope Effects on Shifts

Because fluorine is relatively sensitive to its environment, it exhibits considerable changes in chemical shift when

a nearby atom is replaced by an isotope. As mentioned above, the differential effect of ^{35}Cl versus ^{37}Cl attached to the carbon bearing the ^{19}F is readily resolved, and three-bond effects are also measurable. Studies of isotope shifts in several molecules show that they increase substantially with decreasing temperature, a behavior consistent with an explanation relating them to populations of vibrational energy levels.¹⁹

Replacement of ^{12}C by ^{13}C , either for the atom to which the fluorine is attached or for the carbon one removed, gives a quite measurable shift, usually to lower frequency. A consequence of the isotope effect is that ^{13}C satellites in a fluorine spectrum are not symmetrical about the ^{12}C –F resonance. Table 3 lists some carbon isotope effects on fluorine.

Table 3 Shifts of ^{19}F Resonance (in Hz to Lower Frequency in a Spectrometer at 94.1 MHz) on Substitution of ^{13}C for ^{12}C

Molecule	One-bond shift (Hz)	Two-bond shift (Hz)
$\text{CF}_2=\text{CCl}_2$	9.20	2.50
$\text{CFCl}=\text{CCl}_2$	10.28	2.61
$\text{CF}_3\text{CCl}=\text{CCl}_2$	12.31	0.95
CF_3CCl_3	11.70	1.20
$\text{CF}_2\text{ClCF}_2\text{Cl}$	13.05	1.46
$\text{CF}_3\text{CF}_2\text{CF}_2\text{CCl}=\text{O}$	11.96	1.56
1,1,2,2-Tetrafluoro-3,3-dichlorocyclopropane	10.74	

Isotope shifts also result from the replacement of a nearby hydrogen atom by deuterium or by tritium.^{20,21} Increased shielding of the fluorine in fluorobenzene is produced by substitution of ^2H at any ring position or by substitution for the three hydrogen atoms in a *para*-methyl group. If one is dealing with a nonrigid molecule, there is always the possibility that a change in chemical shift may arise in part from the effect of the isotope on a conformational equilibrium, as well as on an 'intrinsic' property of a specific geometrical structure. This seems to be the situation for trifluoromethylcyclohexane and may also be true for vicinal deuteration in monofluorocyclohexane.²²

3 INDIRECT SPIN–SPIN COUPLING

Spin–spin coupling, usually represented by the symbol J , is an interaction transmitted from one nucleus which has a spin, through the electron cloud in a molecule, and then from the electrons to a second nucleus. The magnitude and sign of J is often characteristic of structural or geometrical relationships between the two nuclei involved, as well as of the nature of bonding of the nuclei. A number of attempts have been made to develop Karplus-type relationships for the angular dependence of coupling of ^{19}F to other nuclei, particularly ^1H or ^{13}C , but the difficulty of treating the effects of substituents, including that of fluorine itself, has led to only modest success for these relationships.

The value of J may be used as a test for the conformation of a fluorinated molecule which may exist in two structures. If the conformations are equilibrating rapidly, the observed J is a

weighted average of the values in the two forms. The question then arises whether a change in conditions of temperature or solvent that affects the conformational equilibrium might also affect the values of J in the individual conformers. Experience indicates that the intrinsic values of J for interactions involving fluorine are more sensitive to conditions than are those for hydrogen, which are almost independent of circumstances.

In fluoropropenes, in which one would not expect conformational changes to occur, the J values in the vinyl moiety change by 1–2 Hz with a temperature change of 150 °C and by a few tenths of a hertz with a change in medium. In $\text{CF}_2=\text{CFCF}=\text{O}$, for which the two-bond constants are 4.0 and <1 Hz in the two conformational isomers frozen out at low temperature, the value at room temperature is 6.0 Hz, well outside the possible range for a weighted average.²³ Solvent and temperature effects have been shown to be appreciable for several types of coupling constant in fluorobenzene and 1,2-difluorobenzene.²⁴

3.1 Trends in Homonuclear Coupling Constants

Coupling constants between fluorine atoms are usually relatively large compared with the homonuclear couplings of hydrogen atoms, and they extend over much longer distances than do those of hydrogen. Some ranges of values are given in Table 4, and J values for several perfluorinated molecules are shown in Figure 1.

Three-bond F–F couplings in substituted ethanes have been found to depend upon the sum of the electronegativities of the other four atoms or groups attached to the two carbon atoms. The higher the sum of the electronegativities, the smaller the magnitude, until for the highest possible value of the sum, corresponding to four fluorine atoms in hexafluoroethane, the value of J has gone through zero and changed sign. Calculations indicate that this behavior is the result of offsetting contributions of opposite sign from various pathways for transmission of spin information. The value of $^3J(\text{F},\text{F})$ for hexafluoroethane may be measured by observing the carbon-13 satellites for those molecules containing one carbon-13 atom, in which the fluorine atoms attached to that carbon atom are no longer equivalent to those attached to ^{12}C .

In the trifluorovinyl group, the values of $^3J_{\text{trans}}$ are surprisingly invariant, ranging only from about 106 to 130 Hz for a wide range of substituents. The values of $^3J_{\text{cis}}$, in

Table 4 Typical Values of Homonuclear Fluorine–Fluorine Coupling Constants

Structure	J (Hz)
Two-bond, F–C–F, aliphatic, noncyclic	170–220
Two-bond, three-carbon ring	150–180
Two-bond, four-carbon ring	190–230
Two-bond, epoxide ring	13–44
Two-bond, oxetane ring, on carbon next to oxygen	84–95
Two-bond, F–C–F, trifluorovinyl	5–100
Three-bond, F–C–C–F, aliphatic	0–30
Three-bond, alkene, <i>trans</i>	–106 to –127
Three-bond, alkene, <i>cis</i>	–24 to –65
Three-bond, aromatic	18–35
Four-bond, aromatic	0–15
Five-bond, aromatic	4–16

Figure 1 Homonuclear ^{19}F – ^{19}F spin–spin coupling constants in three typical unsaturated fluorocarbon molecules. Values of J are given in hertz, adjoining the lines which link the two interacting nuclear types

contrast, vary from 24 to 65 Hz. The largest values are those where a halogen or an oxygen atom is bonded directly to the vinyl group, suggesting that it is the availability of lone-pair electrons that is significant.²⁵

In contrast with proton–proton coupling across an ether oxygen atom, which is usually unresolvable, fluorine–fluorine coupling may be easily observed in a similar situation. Table 5 includes some values for $J(\text{F},\text{F})$ in several simple ethers containing fluorine.

Table 5 Coupling Constants in Fluoroethers

Compound	$^4J(\text{F},\text{F})$ (Hz)	$^2J(\text{F},\text{H})$ (Hz)
CF_3OCF_3	8.2	
$\text{CF}_3\text{OCF}_2\text{CF}_3$	8.5	
CF_3OCHF_2	4.0	69
$\text{CHF}_2\text{OCHFCI}$	5	58, 70
$\text{CHF}_2\text{OCFCl}_2$	4	69
$\text{CHFCIOCF}_2\text{Cl}$	4.5	59
$\text{CF}_3\text{OCFCICHCl}_2$	11	

3.2 Heteronuclear Coupling

3.2.1 Coupling to Hydrogen

Two-bond couplings through carbon are typically 40–60 Hz and are very characteristic in both ^{19}F and ^1H spectra for $-\text{CF}_2\text{H}$, $-\text{CFH}_2$, or $-\text{CFH}$ –groups. Table 5 illustrates the larger values, up to 80 Hz, found when the carbon is attached to an ether oxygen atom. Three-, four-, or five-bond coupling constants in aromatic compounds are about the same as the analogous H–H coupling constants. Three-bond (vicinal) couplings in aliphatic compounds range from very small values up to 15 Hz.

3.2.2 Coupling to Carbon-13

Multiplets produced by ^{19}F coupling in the ^{13}C spectrum of an organic molecule also containing many hydrogen atoms are easily resolved with the aid of proton broadband decoupling.

Values of $^1J(\text{F},\text{C})$ vary from 160 to 400 Hz in magnitude and are negative in sign, an exception to the general rule that one-bond couplings are positive. On comparison of the values in halo-substituted methanes with that in CF_4 , it can be seen from Table 6 that substitution of other halogens for fluorine increases the value of the coupling constant substantially,

Table 6 Values (in Hz) of $^1J(^{19}\text{F}, ^{13}\text{C})$ in Fluoromethanes

		CF_4	–259		
CHF_3	–274	CF_3Cl	–301	CF_3Br	–323
CH_2F_2	–235	CF_2Cl_2	–325	CF_2Br_2	–352
CH_3F	–158	CFCl_3	–337	CFBr_3	–372

whereas substitution of a hydrogen, except for the first one, reduces the value.

In alkenes, the values of $^1J(\text{F},\text{C})$ are about –300 Hz (our work); in the $=\text{CF}_2$ unit of an alkene which is unsymmetrically substituted, the values of the two coupling constants differ from one another. When a fluorine atom is attached to a carbonyl carbon, the value increases to about –370 Hz. In fluorinated aromatics, values lie between –260 for C_6F_6 and –245 for $\text{C}_6\text{H}_5\text{F}$ when there is no other substituent; electron-withdrawing substituents on the ring increase J , while electron-releasing substituents decrease J . It is tempting to say that the former increase the π -electron donation of the fluorine atom to the ring system, whereas the electron-releasing substituents compete with the tendency for this donation.

The sign of $^2J(\text{F},\text{C})$ is positive, and values are typically 20–45 Hz. The value is about 20 Hz for a single fluorine atom in an aliphatic compound. The magnitude increases with substitution of electronegative groups. The value in alkenes depends upon the substitution pattern and is especially large when an electronegative substituent is *trans* to the fluorine. In benzenoid aromatics, the value is 15–25 Hz, except when the carbon bears a substituent, which is thus *ortho* to the fluorine. In cyclopropane rings, the values are small, between 5 and 15 Hz. An especially large value has been found for the two-bond coupling in the molecule $\text{CFBr}=\text{CFBr}$. Similarly, J between the fluorine attached to the carbonyl and the α carbon atom in (4) is 91 Hz, although 2J between the carbonyl carbon and the α fluorine atom in (4) is only 31 Hz. Some other related molecules with very large values of 2J are listed in Table 7.

Table 7 Molecules with Large Values of $^2J(^{19}\text{F}, ^{13}\text{C})$

Compound	2J between α -C and CFO (Hz)	1J in CFO group (Hz)
$\text{CF}_3\text{CF}_2\text{CF}_2\text{CF}=\text{O}$	78	374
$(\text{CF}_3)_2\text{CFCF}=\text{O}$	66	369
$\text{CF}_2\text{ICF}_2\text{OCF}_2\text{CF}=\text{O}$	93	374
$\text{O}=\text{CFCF}_2\text{OCF}_2\text{CF}=\text{O}$	94	372
$(\text{CF}_3)_2\text{C}=\text{CCICF}=\text{O}$	85	355
$\text{CF}_3\text{CIC}=\text{CCICF}=\text{O}$	84	352

3.2.3 Coupling to Phosphorus and Nitrogen

The one-bond coupling constant to ^{31}P is negative and large. For units such as five-coordinate PF_4 – or XYPF_3 or six-coordinate CH_3PF_5 –, values range from about 700 to 1100 Hz.

Often the fluorine nuclei undergo a pseudorotation process which averages out values for the axial and equatorial positions, but if this process is sufficiently slow, a distinction can be made between the coupling constants for the two fluorine positions and the axial value is smaller, for some molecules by as much as 100–150 Hz, than the equatorial value. In five-coordinate compounds in which one ligand is a CF_3 group, $^2J(\text{P},\text{F})$ is 24–88 Hz for the axial position and 107–190 Hz for the equatorial position, providing stereochemical information about the complexes. The barrier to fluxional behavior in a number of complexes has been obtained from analysis of the NMR lineshapes.

The values for one-bond coupling to ^{15}N are usually between 110 and 160 Hz. In *cis*- N_2F_2 , J is 203 Hz, in *trans*- N_2F_2 it is 190 Hz, but in the azide N_3F it is only 58 Hz.²⁶ There is an unusually large value of 53 Hz for $^2J(\text{F},\text{N})$ in 2-fluoropyridine, perhaps attributable to transmission via unshared electrons. No large couplings are found for adjacent substituents in benzene: in 2-fluoronitrobenzene, $^3J(\text{F},\text{N})$ is 2.66 Hz; and in 2-fluoroaniline, it is about 0.5 Hz. In 2- CF_3 -aniline, $^4J(\text{F},\text{N})$ is 1.68 Hz. In 5-fluorouracil, the two values of 3J are 1.12 and 1.66 Hz.

3.2.4 Coupling to Metals

Fluorine forms bonds to a wide variety of metals. In several binary compounds with nuclei having spin $\frac{1}{2}$ or small quadrupole moments, splittings can be resolved and values of J can be measured. Examples are TiF_6^{2-} , $J = 34$ Hz, and NbF_6^- , $J = 335$ Hz. Mercury compounds show positive two-bond couplings with magnitudes up to more than 2000 Hz and three-bond couplings as large as several hundred hertz. Some other examples are given in Table 8.

In TeF_6 , $^1J(^{125}\text{Te}, ^{19}\text{F})$ is 3746 Hz and in TeF_7^- it is 2876 Hz.²⁷ The smaller value in the latter has been attributed to weaker, more polar bonds. That there is only a single value of J and only a single shift for all six fluorine atoms indicates rapid exchange between axial and equatorial positions. It is interesting that the number of naturally occurring isotopes of tellurium leads to multiple, slightly shifted, fluorine resonances.

3.3 Long-Range Coupling

It has been proposed that many of the examples of coupling between two fluorine nuclei which are separated by a number of bonds (four, five, six or more) may result from overlap of electronic orbitals occupied by electrons which are unshared and therefore not involved in normal covalent

bonding. The term applied to this effect, ‘through space’, is somewhat misleading, since only the anisotropic dipole–dipole interaction is effective through ‘empty’ space. All isotropic coupling is transmitted in some way by electrons, either in bonds or in unshared pairs.

The idea of transmission of the indirect coupling through electrons not involved in bonds was proposed by Petrakis and Sederholm.²⁸ It has since been extended to systems involving nuclei other than fluorine.

Coupling via nonbonding electrons may be invoked to explain the temperature dependence of $^4J(\text{F},\text{F})$ in $\text{CF}_2\text{ClCFClCFCl}_2$ (**5**). As the temperature is lowered from room temperature to -100°C , the value of the coupling between the fluorine atom in CFCl_2 and one of the fluorine atoms in the CF_2Cl unit increases from 17 to 28 Hz, whereas the other 4J decreases from about 13 to 12 Hz. The large coupling at low temperature can be assigned to two fluorine atoms forced to be closer together by the increasing effects of steric repulsions with decreasing temperature, as represented in the diagram for (**5**).

Another example which can be explained by the ‘through-space’ mechanism involves coupling of the fluorine atoms in an oxetane ring with the *ortho* fluorine atoms in a pentaphenyl group substituted in the ring. The molecule (**6**) exists in two isomeric forms, differing in whether the pentafluorophenyl group and the chlorine atom are on the same side or on opposite sides of the ring. In one isomer, $J(\text{F}_A, \text{F}_D)$ is 1.3, $J(\text{F}_B, \text{F}_D)$ is 10.7, and $J(\text{F}_C, \text{F}_D)$ is 11.4 Hz. In the other isomer, $J(\text{F}_A, \text{F}_D)$ is 7.5, $J(\text{F}_B, \text{F}_D)$ is 1.4, and $J(\text{F}_C, \text{F}_D)$ is 0.9 Hz.

There are other examples of long-range coupling which cannot be explained by direct orbital overlap, but are probably associated with electron delocalization in π orbitals. Thus the stereochemistry of fluorinated alkenes and dienes is related to $^3J(\text{F},\text{C})$ in a way not fully explained by nuclear proximity.²⁹

Outstanding among the interactions transmitted by π orbitals are those across aromatic ring systems. A number of these have been related to studies of molecular conformation. In 3,5-dichlorobenzyl fluoride, as an example, $^6J(\text{F},\text{H})$ is related to the rotational orientation of the $-\text{CH}_2\text{F}$ group with respect to the ring.³⁰ Long-range C–F coupling in derivatives of benzoic acid and benzoyl fluoride are related experimentally and theoretically to the dihedral twist angles of the substituent-to-ring C–C bond.³¹ A study of fluorinated methyl phenyl sulfoxides showed that $^5J(\text{F},\text{H})$, $^4J(\text{F},\text{C})$, $^5J(\text{F},\text{C})$, and $^6J(\text{F},\text{C})$ are dependent upon the conformation about the sulfur atom.³²

Table 8 Fluorine–Metal Coupling Constants

Species	Solvent	Coupling Constant (magnitude) (Hz)
VOF_3	THF	110
VOF_4^-	CH_3CN	86
$\text{VO}(\text{CF}_3\text{CO})_3\text{F}^-$	CH_3CN	80
VO_2ClF^-	CH_3CN	207
VO_2F_2^-	CH_3CN	272
NbOF_4^-	CH_3CN	410
$(\text{CF}_3)_2\text{Hg}$	CH_2Cl_2	1263

4 RELAXATION; NUCLEAR OVERHAUSER EFFECTS

Fluorine-19 nuclei may undergo spin-lattice relaxation by the direct dipolar mechanism, in much the same way as do protons. However, because of the presence of unshared electrons, spin-rotation (SR) and chemical shift anisotropy (CSA) mechanisms also contribute to the relaxation of ^{19}F . Because of the additional relaxation pathways, T_1 values are often substantially smaller than for protons in a similar environment.

Early workers reported that the CSA contribution is negligible and that spin rotation predominates. This is true for molecules such as CF_4 or SF_6 , which are small and freely rotating, and for measurements at 2.4 T or lower magnetic field strength. Since the spin-rotation relaxation time decreases with increasing temperature, whereas the dipole-dipole relaxation time increases with increasing temperature, a maximum may be observed for T_1 as a function of temperature, as has been found, for example, for *o*-fluoroiodobenzene at about 110 °C.

Spin-rotation interaction constants can be calculated from the paramagnetic term of the NMR shielding constant.³³ They can also be measured by molecular beam methods, and the values for HF, F_2 , SiF_5 , CF_4 , and CHF_3 show good agreement by the two methods. It should also be possible to calculate the spin-rotation constants from measured spin-lattice relaxation times, but this requires knowledge of the correlation time, and reasonable guesses for the latter give values of the constant too large by a factor of 2 to 3.

Rapid spin-spin relaxation is associated with broadening of spectral lines, such as is caused by inhibition of motion, as occurs with macromolecules. The extent of broadening is related to the anisotropy of the chemical shift, which is often large for ^{19}F . Since the CSA contribution increases with field, the broadening is greater at higher fields, often offsetting the improvement in sensitivity and resolution expected, such as by going to a frequency of 470 MHz. Since macromolecules do rotate more slowly, the SR contribution for the ^{19}F relaxation in them is small, except possibly for freely rotating CF_3 groups.

The nuclear Overhauser effect (NOE) of fluorine nuclei is much like that of protons. Most applications of the NOE to fluorine have been heteronuclear, where the close approach of one or more particular hydrogens atoms to a fluorine atom is monitored. In macromolecules, dipolar interactions are often the predominant T_1 relaxation mechanism, and saturation of protons should fully invert the normal ^{19}F intensities. Under circumstances where the T_1 of the ^{19}F nucleus is shorter than that of the ^1H , it is preferable in a one-dimensional NOE experiment to use the ^{19}F as the source of the Overhauser transfer so that irradiation maintains the nonequilibrium population.

Indirect Overhauser enhancements through ^{19}F from ^1H to ^1H or from ^1H to ^{13}C have been obtained for several cyclic compounds.³⁴ In NOE difference spectra, antiphase doublets were observed for protons undergoing simultaneous scalar coupling and dipolar relaxation with ^{19}F . The geometrical factors inherent in the three-spin NOE were utilized in conformational analysis. NOE measurements have also been used to confirm the proximity of hydrogen nuclei to fluorine

nuclei in some tetrahydroindazole derivatives where long-range coupling between these nuclei was suspected of being the result of a 'through-space' interaction.³⁵

It is interesting that pioneering work in the analysis of the NOE was the application by Solomon and Bloembergen³⁶ to the HF system. Because of the very large value of $^1J(\text{F,H})$ in this molecule (more than 600 Hz), there is relaxation by interrupted scalar coupling, which produces a negative enhancement instead of the positive intensity change expected for the dipole-dipole mechanism.

5 APPLICATIONS TO BIOCHEMICAL PROBLEMS

By virtue of the circumstances that there is almost never any fluorine background in living systems and that fluorine shifts are quite sensitive to the environment, applications of ^{19}F NMR to biochemical problems have been extensive. Several reviews have appeared.^{37,38}

Fluorine NMR has been applied in the investigations of several types of system, perhaps most extensively to proteins. Pioneer work in this field was that of Sykes and Hull,³⁹ who applied ^{19}F relaxation measurements to the study of motions of groups in proteins. Alkaline phosphatase was labeled with fluorotyrosine residues. Both overall rotation of the protein and internal rotation of the aromatic ring contribute to ^{19}F relaxation, which includes a substantial CSA component. Two of the tyrosine rings relax by chemical exchange, indicating that they are free to rotate, and one of the tyrosines relaxes faster in $^1\text{H}_2\text{O}$ than in $^2\text{H}_2\text{O}$, indicating that it is exposed to the solvent.

In other systems, the nature of binding of small molecules to proteins has been studied. On binding of an inhibitor such as cytidine monophosphate (CMP) to ribonuclease S trifluoroacetylated at lysines-1 and -7, the fluorine resonance assigned to lysine-7 splits and becomes pH dependent.⁴⁰ This change could, of course, come either directly from contact of the inhibitor with the lysine or indirectly as a result of a conformational change of the protein caused by the inhibitor. A summary of the considerations involved in using fluorine as a tool in the investigation of ligand binding has been provided by Gerig.⁴¹

Several efforts have been made recently to provide a theoretical analysis of the effects of the environment on fluorine nuclei, and to explain the chemical shift effects of up to 20 ppm observed when a protein folds about the fluorine indicators.^{42,43} The conclusion has been that the principal influence is via electrostatic interactions, and that this influence is effective in proportion to the magnitude of the paramagnetic term in the nuclear shielding expression.

Fluorine shifts and coupling constants are valuable in the conformational analysis of carbohydrates. Pioneering work in this area was that of Hall.⁴⁴ The spectrum of 6-deoxy-6-fluoro-D-glucose has been carefully analyzed in terms of the conformer population in various solvents; this analysis illustrates the very important point that, although the resonance frequency of ^{19}F is very far removed from that of ^1H , it may represent the X part of a non-first-order system, such as the ABCX system in this molecule, and a first-order interpretation is misleading.⁴⁵

Fluorine-19 has been used as an indicator of the presence of various free ions in living systems. 5-Fluoro derivatives of

the molecule APTRA (*o*-aminophenol-*N,N,O*-triacetic acid) give separate resonances for free and magnesium-bound forms of the indicator, and knowledge of the equilibrium constants involved and the ratios of the two peaks permits evaluation of the free magnesium concentration. The 4-fluoro derivative of APTRA as well as fluorocitrate are in fast exchange with Mg^{2+} , giving a resonance which is at the weighted-average position of the free and magnesium-bound indicator resonances.⁴⁶ Chelators have also been employed to assess calcium concentrations. One, known as 5F RBAPTA, a 1,2-diphenoxyethane derivative, provides slow exchange with Ca^{2+} , and is designed to give rapid spin-lattice relaxation because it contains a *t*-butyl group adjacent to the fluorine.⁴⁷

6 APPLICATIONS OF SPECIAL TECHNIQUES

Two- or three-dimensional ^{19}F correlation spectroscopy provides an attractive means of structure studies, especially for highly fluorinated materials. By firmly establishing coupling connections in a molecule which typically has a very complex spectrum, often with overlapping and non-first-order patterns, these techniques facilitate the relationship of resonances to structural features. COSY has been applied to the assignment of resonances and the study of microstructure of fluorinated polymers.⁴⁸

Figure 2 shows an illustrative COSY spectrum of a mixture of three chlorofluorocarbon isomers. From the one-dimensional ^{19}F spectrum, it was not possible to assign the various multiplets unambiguously or even to be certain that

Figure 2 Homonuclear ^{19}F - ^{19}F COSY (correlation spectroscopy) spectrum of a mixture of three isomers. Formulas of the three components of the mixture are shown and assignments of the resonances are indicated by letters. The spectrometer frequency was 282 MHz. The axes are labeled with arbitrary scales based on the carrier frequency of the spectrometer

the mixture did not contain some six-carbon as well as four-carbon components. Based on inspection of the off-diagonal correlations in the COSY spectrum, combined with consideration of the multiplets in the one-dimensional spectrum and the symmetries of possible components, definitive assignments of structure could be made.

Because of the difficulties of chromatographic resolution of mixtures of isomers of compounds of this type, it is thus very helpful to be able to sort out the resonances belonging to each of the components in a mixture. Hartmann-Hahn-based experiments (HOHAHA or TOCSY) are difficult to apply to a typical fluorinated molecule, especially at the fields now in use, because of the difficulty of maintaining a spin lock over the very wide frequency range required, and a COSY or relayed COSY sequence may be more appropriate.⁴⁹ Even here, however, problems may arise from the spectral widths often encountered, because of the many data points in each dimension required to ensure adequate resolution. Thus selective excitation or selective polarization transfer, such as is possible with the pulse-shaping capabilities of modern instruments, is helpful in reducing the large size of the data arrays required.

By use of appropriate correlation experiments optimized for coupling constants of various magnitudes, it is also possible to determine the relative signs of coupling constants from the sense of the skew in the off-diagonal peaks.⁵⁰

Two-dimensional heteronuclear NOE spectroscopy can be applied to structural studies of ^{19}F -labeled oligodeoxyribonucleotides. In macromolecules, chemical shift anisotropy dominates the spin-spin relaxation of ^{19}F , although T_1 relaxation is primarily dipolar in nature. As a result, the fluorine lines are broad, and small spin-spin couplings to hydrogen cannot be resolved. Since the Overhauser enhancement ratio for ^{19}F - $\{^1\text{H}\}$ in a large molecule is -1 , this technique affords a means of determining spatial adjacencies.⁵¹

In fluorine-labeled molecules such as steroids, there may be many proton spin-spin interactions with the label atom, and it is experimentally difficult to unravel the splittings in the fluorine spectrum by selective decoupling of protons. Two-dimensional heteronuclear correlation experiments, analogous to homonuclear COSY, can be used to establish long-range couplings, from which conformational information can be obtained.⁵² In a number of steroids, small splittings caused by protons remained unresolved in the proton spectrum because of their number and the widths of the lines. In COSY, all interactions down to the limit imposed by the intrinsic linewidth can be resolved, and long-range couplings of 0.5 Hz or less are observable. Combining the information from the coupling constants with known effects on chemical shifts made it possible to assign the NMR spectra completely and to derive complete steroid structures.

As another means to establish connectivities, one might examine the proton spectrum with the fluorine decoupled; in the absence of a fluorine decoupler, this has been done by using the proton decoupler as the source of the observe signal and pulsing the fluorine signal from the transmitter between the acquisition intervals in the FID. Both COSY and one-dimensional experiments have been performed in this way.⁵³

Finally, an alternative approach to unraveling complex fluorine-proton interactions involves the use of fluorine decoupling achieved by a spin-flip technique. The output of two channels of a dual-channel spectrometer is combined and

applied to the high-frequency coil in a probe. During the period of acquisition of the proton signals, pulses from the fluorine channel, applied in the empty time slots, are phase cycled according to an XY-4 or XY-32 scheme, spreading the irradiation frequency over the needed wide bandwidth.⁵⁴

1 INTRODUCTION

The fullerenes, which by definition are polyhedral, closed cages of n carbons having twelve pentagonal and $(n/2 - 10)$ hexagonal faces, have been proposed to be important constituents of soots and interstellar dust. In addition to the more common single-walled closed cage compounds such as C₆₀ and C₇₀, multiple-walled cage structures are also known, with onion-like structures of up to twenty concentric layers having been demonstrated to exist. Among the related compounds are nanotubes, or elongated fullerenes; single-walled and multi-walled, capped or open-ended varieties exist. There also exist endohedral or *incar*-fullerenes that have atoms or small molecules trapped inside the cages. In addition, there are intercalation complexes of fullerenes with atoms or molecules held in the interstitial crystal sites. The intercalation complexes with alkali metal atoms have attracted much attention, especially A₃C₆₀ species with A=K, Rb, or Cs, as they are superconductors with transition temperatures, T_c , above 30 K. Several books and reviews on the chemistry and physics of fullerenes are given in the references¹⁻⁵ to provide further information on this interesting class of compounds.

Solid state nuclear magnetic resonance, NMR, studies beyond simple MAS spectra (magic angle spinning) on this class of compounds have been mainly limited to studies on C₆₀, C₇₀, and intercalation complexes of C₆₀, mainly due to the sample requirements of solid state NMR. These studies have provided insight into the structure, phase transitions, dynamics, and electronic properties of these compounds. There has been one solid state NMR study of the dynamics of C₇₆ as well as a recent study on nanotubes. This article will focus on these

studies by solid state NMR and the information they have provided.

2 HISTORY OF FULLERENE DISCOVERY

Until relatively recently it was an accepted fact that pure carbon existed in one of two allotropic forms: graphite and diamond, both having extended structures, the first with sp²-hybridized carbons and the second with sp³-hybridized carbons. This changed in 1984 when the first spectroscopic evidence of a molecular form of carbon was published.⁶

A mass spectrum of laser vaporized graphite published by researchers at Exxon showed the existence of a number of carbon clusters with the maximum intensity being C₆₀. About a year later Harold Kroto's group at Sussex University in the UK found conditions where C₆₀ was produced nearly exclusively.⁷

Richard Smalley of Rice University proposed the familiar truncated icosahedral or soccer ball structure for C₆₀, shown in Figure 1a, and the name buckminsterfullerene. This was not the first time such a structure had been suggested, however, as there had been a number of theoretical studies on the structure, stability, and properties of this C₆₀ structure prior to 1984.⁸⁻¹⁰

The next advance in the study of C₆₀ came in 1990 when Krätschmer, Fostiropoulos, and Huffman developed a method to make macroscopic quantities of C₆₀ and obtained infrared, IR, and X-ray powder diffraction spectra that supported the predicted structure.¹¹ The subsequent work on the isolation and purification of C₆₀ also led to the isolation of the first of the higher fullerenes, C₇₀, shown in Figure 1b, in which a band of ten carbons is added around the equator of the C₆₀ structure. The confirmation of the C₆₀ and C₇₀ structures followed shortly thereafter, with ¹³C solution NMR unambiguously confirming the proposed structure of both compounds. C₆₀ showed the expected single line at 143 ppm for all 60 carbons while C₇₀, with *D*_{5h} symmetry, showed five lines between 130 and 150 ppm in a 10:20:10:20:10 ratio as expected.¹² The assignment of these resonances to the five groups of carbon atoms, labeled C_a through C_e in Figure 1b, was confirmed by a solution ¹³C INADEQUATE spectrum (Incredible Natural Abundance Double QUantum Transfer Experiment).¹³ Continuing work led to the isolation of a number of other fullerenes, both smaller and larger than the dominant C₆₀ compound.

Richard Smalley and Robert Curl Jr. from Rice University in Houston, Texas along with Harold Kroto from Sussex University in England were awarded the 1996 Nobel Prize in Chemistry for their work on the discovery of fullerenes.

3 STUDIES ON PURE C₆₀

Before going into details on the NMR studies of pure C₆₀, some information on the crystal habitat is necessary. At room temperature C₆₀ is known to exist as an orientationally disordered face-centered cubic (fcc) structure. There is a phase transition, observed by both differential scanning calorimetry and x-ray powder diffraction, at about 250 K to a simple cubic (sc) with orientational order.

Solid state NMR provided the first measure of the bond lengths of C₆₀ through the ¹³C-¹³C dipolar coupling in

Figure 1 Structures of (a) C_{60} and (b) C_{70} . In C_{70} , carbons are labeled C_a – C_e , based on their chemical shifts

partially enriched C_{60} .¹⁴ This was accomplished using the Carr-Purcell Meiboom-Gill pulse sequence, which selectively removes the chemical shift anisotropy, CSA, while retaining the dipolar coupling. The measurement indicated that there were two different bond lengths, 1.45 Å and 1.40 Å, in a 2 : 1 ratio, consistent with the proposed structure. This result can be compared with a subsequent gas phase electron diffraction measurement of 1.458 Å for a bond joining two six-membered rings and 1.401 Å for the bond joining the five- and six-membered rings.¹⁵ Similar distances have also been obtained by low temperature single crystal x-ray diffraction and by low temperature powder neutron diffraction.

In addition to the structural studies, work has been completed on the dynamics of C_{60} .^{16,17} The static ^{13}C NMR powder patterns obtained as a function of temperature are shown in Figure 2. At room temperature a narrow line indicative of rapid, isotropic rotation is obtained. As the temperature is lowered a broad feature appears in the spectrum. Below 100 K the static spectrum is dominated with the broad anisotropic powder pattern characteristic of a molecule that is stationary on the NMR timescale, meaning that the correlation time for isotropic reorientation is large compared to the inverse of the static linewidth. There is no evidence of the 250 K phase transition from either the static or MAS spectrum. There is sometimes a small percentage of the material that is still motionally averaged as evidenced by the sharp peak superimposed on the broad CSA pattern. The intensity of this feature is a function of the purity of the sample and is believed to be due to molecules having low energy barriers to reorientation when they are near structural defects in the crystal structure due to the presence of impurities.

Additional information is obtained by looking at the T_1 relaxation times, generally obtained by saturation recovery methods, as a function of temperature, as shown in Figure 3.¹⁷ In T_1 measurements a phase transition can be manifested as a discontinuity in the curve of T_1 versus temperature. This is the case in C_{60} . The T_1 data were fit to a model of going from essentially unhindered, rapid isotropic motion in the high temperature fcc phase to a reorientation restricted to jumping between symmetry related orientations in the low temperature sc form. Further analysis of the temperature dependence of the motion, using the fact that the dominant relaxation mechanism is the CSA, provided an activation barrier to rotation of about 5.9 J/mol in the fcc phase and from 17 to 25 J/mol in the sc form.

Figure 2 Static solid state ^{13}C NMR spectrum of C_{60} as a function of temperature. The spectra change from a lineshape indicative of rapid isotropic motion at 295 K to one of no molecular motion on the NMR timescale at 77 K. (Reproduced by permission of the American Chemical Society from Ref.¹⁶)

The low temperature powder pattern also gives the principal components of the chemical shift tensor, which can be used to provide insight into the electronic structure. These have been measured to be 220, 186, and 40 ppm¹⁶ (or 213, 182,

Figure 3 The temperature dependence of the ^{13}C T_1 relaxation time of solid C_{60} at a field strength of 9.39 T. The 260 K phase transition is responsible for the discontinuity in the curve. Squares are T_1 values obtained from a single exponential fit of the T_1 saturation recovery data; circles are the average of the two T_1 values obtained from a double exponential fitting. The solid line is the fit of the data for the sc phase between 193 and 243 K, based on a model of relaxation dominated by the CSA. The dashed line is the fit of the data above 263 K for the sample in the fcc phase. (Reproduced by permission of the American Physical Society from Ref.¹⁷)

and 33 ppm).¹⁷ These numbers are typical aromatic chemical shift tensor numbers with the δ_{33} component showing the characteristic shift to a higher value expected due to the strain of the five-membered rings. The principal values are similar to the values for the five-membered ring carbons in other aromatic systems, such as corannulene¹⁸ (224, 177, and 6 ppm), acenaphthene¹⁹ (213, 195, and 13 ppm), and pyracene²⁰ (202, 192, and 24 ppm). In contrast, the δ_{33} components for bridgehead carbons in six-membered ring compounds are usually less than 0 ppm, and in the case of coronene it is measured at -38 ppm for the innermost carbon.¹⁸

4 STUDIES ON PURE C_{70}

There are three solid state NMR studies, all published in 1993, that have measured the relaxation data, MAS spectra, and/or the static powder pattern as a function of temperature on samples of greater than 98% pure C_{70} .^{21–23} While the basic dynamic interpretation of the spectra are consistent between these three reports, there are significant differences.

C_{70} has three known phases.²⁴ Above 330 K it exists in either an fcc or a hexagonal closed packed (hcp) structure with complete rotational disorder, similar to the room temperature phase of C_{60} . Between about 280 and 330 K the crystal structure is rhombohedral with the long axis directed essentially along the [111] crystal axis; rotational disorder exists perpendicular to this axis. A molecular dynamics simulation predicted that the motion in this phase is not pure uniaxial rotation about the long axis, but includes a precession of the long axis about this crystal axis.²⁵ Below 280 K

the structure becomes monoclinic with orientational ordering; however, no details are known about the molecular orientation. It has also been determined that in order to obtain the equilibrium low temperature ordered phase, the crystal must be cooled extremely slowly (e.g., over a matter of many hours) from the high temperature phase through the lower temperature transition. If cooled quickly, as in sublimation, the two high temperature phases with their rotational freedom have been shown to persist until very low temperatures, even down to 10 K. Therefore, careful treatment of the sample is necessary to ensure knowledge of its phase.

NMR provides some evidence of the phase transitions. Upon increasing the temperature of a sample that has first been cooled slowly from 300 to 50 K, the MAS spectra as a function of temperature showed a small shift in the isotropic positions of several of the resonances at approximately 273 K and 323 K, consistent with the known phase transition temperatures.²⁴ The T_1 temperature dependence in one study²² showed a deviation from the expected curve at about 280 K; in the other study²³ the T_1 measurements did not show any significant discontinuities at this phase transition temperatures.

There have been two static 1D NMR measurements as a function of temperature. In the first, by Blinc et al.,²¹ the static lineshape was measured as a function of temperature from 450 to 50 K at a ^{13}C frequency of 67.89 MHz. There were two increases in the width of the static pattern as the temperature was lowered: from about 1 kHz above 300 K to nearly 3 kHz below 200 K with the full static linewidth of about 12 kHz being reached below 100 K. The spectra of the rhombohedral phase between 270 and 120 K were fit according to ordering of the sample along [111] crystallographic axis and the onset of uniaxial rotation with precession. Those between 120 and 50 K were fit as a gradual slowing of the uniaxial rotation, with the lowest temperature lineshape simulated as the overlap of five axially symmetric tensors. The lineshapes of these intermediate temperature spectra, however, were not the expected overlap of five axially symmetric patterns, and are not consistent, both in terms of spectral features and linewidths, with the experimental results of the other two studies. Maniwa et al.²² also measured the 1D static powder pattern as a function of temperature between 340 and 77 K at a ^{13}C frequency of 65.5 MHz. From a single tensor fit of the 77 K spectrum the principal values were estimated to be 225, 200, and 25 ppm, values similar to those of C_{60} . The spectra at intermediate temperatures were simulated as five overlapping axially symmetric tensors using the above measured static principal values, adjusted to axial symmetry for the rotation about the long axis, and assuming the δ_{33} component is oriented perpendicular to the carbon cage. Therefore, the same tensor is averaged by a different angle, as the angle between the long axis and the δ_{33} component is different for each of the five inequivalent positions. There were no values for the measured anisotropy reported. The simulation was similar to the experiment, as can be seen in Figure 4, and differences were accounted for by the fact that the predicted precession of the long axis, which would lead to a further narrowing of the axially symmetric tensor, was not included in the simulation.

Tycko et al.²³ studied C_{70} with a slow spinning sideband intensity analysis between 320 and 230 K, a 2D MAS/CSA correlation experiment at 233 K, and a static 1D measurement

Figure 4 Observed (thick line) and simulated (thin line) ^{13}C static spectrum of C_{70} at 295 K at a frequency of 65.5 MHz. The simulation assumes five overlapping axially symmetric shift tensors based on static tensor components of 225, 200, 20 ppm, and angles of 38, 51, 78, 66, and 78° between the rotation axis and the δ_{33} component for carbons C_a – C_e , respectively. (Reproduced by permission of the Physical Society of Japan from Ref.²²)

Figure 5 Slow spinning ^{13}C MAS NMR spectrum of C_{70} at 283 K and a spin rate of 1.2 KHz along with the simulated spectra using spinning sideband intensities from a Herzfeld-Berger analysis and information from a 2D MAS/CSA experiment. (Reproduced by permission of the American Institute of Physics from Ref.²³)

at 50 K. The 2D MAS/CSA experiment separates the individual powder patterns based in the 2D space by the isotropic chemical shift values. A representative spinning sideband pattern at 283 K, along with its simulation based on both a Herzfeld-Berger spinning sideband intensity analysis²⁶ and the values from the 2D experiment, are shown in Figure 5. From these simulations, the anisotropy (defined as $\Delta\sigma = \sigma_{\perp} - \sigma_{\parallel}$) of the five tensors at 230 K were reported as 162, 27, -42, -72, and -77 ppm for carbons C_a – C_e , respectively. In all cases the spectra are axially symmetric, indicative of the uniaxial rotation expected at this temperature. Based on a full anisotropy of 200 ppm for a static sample taken from the 50 K static pattern, the authors showed that the scaling of the anisotropy is consistent with that expected for uniaxial rotation about the long axis assuming the δ_{33} component is normal to the cage.

In summary, the variations in the ^{13}C NMR lineshape as a function of temperature from a sample of pure C_{70}

are rich in information about the motional characteristics of the three known phases. The NMR studies give a consistent picture of the molecular motion first changing from anisotropic rotation to uniaxial rotation about the long axis, with a slight precession. This is followed by the transformation into the low temperature phase in which there is no molecular motion. However, the principal values of the five inequivalent carbons of C_{70} have not yet been obtained. Accurate tensor components for these five carbons should be obtainable from a 2D spectrum in which the CSA of individual carbons is separated by their isotropic values, provided that the experiment is performed below 100 K and that care is taken in the sample cooling procedure.

5 STUDIES ON PURE HIGHER FULLERENES

There is much less information, from any source, on the structure and dynamics of the larger fullerenes. For C_{76} , a single solid state NMR study exists.²⁷ The C_{76} molecule has a chiral D_2 structure calculated to have three distinct molecular axes of lengths 8.75, 7.50 and 6.54 Å. Solution NMR shows nineteen resonances in the range of 130–150 ppm. The solid state NMR lineshape gives evidence that at room temperature C_{76} also undergoes rapid, isotropic motion at room temperature, but as it is cooled there is no evidence of going first to uniaxial rotation as in C_{70} . Instead, the spectra indicate a relatively sharp transition between anisotropic rotation and a static molecule between approximately 170 and 135 K. The T_1 temperature dependence also showed a slight discontinuity in the range of 170 K; this may be evidence of a still unknown phase transition.

6 STUDIES ON NANOTUBES

Due to recent advancements in the procedures to make and purify nanotubes, samples of sufficient size and uniformity are now becoming available for study. The single walled nanotube (SWNT) structures can be thought of as a tube made from a single layer graphite sheet that has been rolled to form a tube; the ends can be open or closed with a semi-fullerene cap. Nanotubes are characterized by their diameters and their helicity, which is a measure of how the hexagons wind around the surface. Several representative structures of capped nanotubes with different helicities are given in Figure 6. Nanotubes can exhibit either semiconducting or metallic electronic properties depending on these two properties. The SWNT also self assemble into larger structures known as bundles or ropes; the manner of this assembly is also believed to affect the properties of the nanotube.

The first solid state NMR study of the CSA and T_1 relaxation behavior of a SWNT has very recently appeared in the literature.²⁸ Due to the manner of production of these structures, it is very important to either purify the samples to remove traces of paramagnetic metal catalysts that lead to extensive broadening of the powder pattern or to perform the synthesis with alternative catalysts. The reported static and MAS spectra of a SWNT sample with a diameter of 0.85 nm are given in Figure 7. The MAS has a single resolved peak at 124 ppm with a full width at half height of about

Figure 6 Sample structures of nanotubes of different diameters and helicity. (Reproduced by permission of Imperial College Press from Ref.², p. 33)

Figure 7 The static and MAS (at a spin rate of 11.7 KHz) solid state ^{13}C spectra of a nanotube of average diameter 0.85 nm. A fit of the static powder pattern to a single tensor is also shown. (Reproduced by permission of the American Association for the Advancement of Science from Ref.²⁸)

30 ppm; fitting the room temperature static pattern as a single tensor yielded the tensor principal values of 195, 160 and 17 ppm. These principal values again show the expected increase in the δ_{33} component associated with the strain of the non-planar environment. The T_1 relaxation behavior of this sample was best fit to a double exponential function with the slower relaxation component being attributed to tubes with metallic characteristics and the longer component due to tubes exhibiting semi-conducting behavior. However, both components showed the linear relationships with temperature expected for the Korringa relaxation (see discussion in next section) through the conducting electron band of metallic samples.

Further NMR studies on nanotubes should now follow as homogenous samples are becoming available in large enough quantities, allowing for a better understanding of the properties of these materials.

7 STUDIES ON THE INTERCALATION COMPLEXES OF FULLERENES

There are many examples of intercalation complexes of C_{60} . In the room temperature fcc structure of C_{60} there are two tetrahedral sites and one octahedral site per molecule with estimated radii of 1.1 and 2.1 Å, respectively. Both sites are large enough to hold most atoms and even small molecules.

The most widely studied group of intercalation complexes is the alkali fullerenes, A_xC_{60} , ionic solids comprised of A^+ and C_{60}^{x-} ions. The $x = 1, 3, 4$, and 6 species have been isolated and characterized. Electronically, the lowest unoccupied molecular orbital (LUMO) of the parent C_{60} is triply degenerate. Therefore, both the neutral species with an empty LUMO and the C_{60}^{6-} ion with a full LUMO should be, and are, insulators. The others, with a partially full conduction band, are expected to have metallic behavior. However, no clear evidence of metallic behavior has been found in either the A_1 or A_4 species. The A_3 species have been shown to be conductors and superconductors,²⁹ with transition temperatures (T_c 's) measured to be above 30 K.³⁰ These are among the highest T_c 's known with the exception of the so-called "room temperature" copper oxide superconductors which have temperatures of about 150 K. For this reason the A_3C_{60} fullerenes have attracted the most attention. A brief summary of the solid state NMR of A_3C_{60} follows; a more comprehensive treatment of the alkali fullerenes, including details of the mechanisms of superconductivity, is referenced.³¹

Before going into details about the NMR results on these compounds, two effects of the conduction band on the NMR must be discussed. The first is the Knight shift, which is a shift in the resonance frequency observed in metals due to the hyperfine coupling of the nucleus to the conducting band electrons.³² The measured resonance frequency is the sum of the chemical shift and the Knight shift. This electron-nuclear coupling also dominates the T_1 relaxation in these compounds. The linear relationship observed between the T_1 relaxation time and temperature in conducting systems is quantified by the Korringa³³ relationship, and is often reported as a plot of $(1/T_1T)$ versus T . Neither of these effects is observed in the superconducting state, leading to observable changes at T_c in plots of the temperature dependence of both the shift and the T_1 relaxation time.

The fcc structure of K_3C_{60} , as well as the other A_3C_{60} structures, is shown in Figure 8.³⁴ The most significant difference between this structure and that of pure C_{60} is that the C_{60} entities are no longer orientationally disordered, but are oriented with a hexagonal face directed towards the tetrahedral site, maximizing its size. A series of spectra of the A_3C_{60} compounds are shown in Figure 9. In the NMR of the alkali metal atoms, differentiation of the atoms in the tetrahedral and octahedral sites, as well as a splitting of the tetrahedral peak, is observed. The two tetrahedral peaks are believed to be due to crystal distortions and the splittings can be removed by going to higher temperatures. Diffraction studies have not shown any evidence of this distortion. The measured ^{13}C spectra show the effect of decreased motional freedom of the C_{60} ion as the size of the alkali metal increases (radii of the alkali ions are: K^+ 1.33 Å, Rb^+ 1.48 Å, Cs^+ 1.67 Å). In addition, the observed Knight shift is relatively small, with

Figure 8 Structure of K_3C_{60} alkali fulleride. The open and hatched spheres represent the potassium at the tetrahedral and octahedral sites, respectively. (Reproduced by permission of the Nature Publishing Group from Ref.³⁴)

the sum of the Knight shift and any change in the chemical shift from neutral C_{60} being only 30–50 ppm. Most calculations of the expected Knight shift in these compounds are much larger. The temperature dependence of both the total shift (Knight and chemical) and the T_1 relaxation time are shown in Figure 10 for the case of Rb_2CsC_{60} , which has a T_c of about 30 K. All the plots show the expected changes

at this temperature. Tycko et al.³⁵ has used the value of T_1T in the normal conducting state to make a rough estimation of the density of electronic states at the Fermi level (about 20 eV^{-1} per C_{60} ion). The Arrhenius behavior of the T_1 in the superconducting state was also used to obtain a measure of the electronic energy gap ($3T_c$ for K_3C_{60} and $4T_c$ for Rb_3C_{60}).

The above shows the important information on the structure and electronic properties of the alkali fullerides solid state NMR has provided. However, many questions about the structure and electronic properties remain unanswered. Also, contradictions in the experimental data still exist, and must be reconciled before the electronic behavior of this class of compounds can be understood.

8 CONCLUDING REMARKS

Solid state NMR has been shown to be a powerful tool in the study of the structure, phase transitions, dynamics, and electronic properties of the C_{60} , C_{70} , and several intercalation complexes of C_{60} and should continue to contribute to the study of these materials in the future. There still exist unresolved issues in the study of the alkali fullerides that solid state NMR can address. Higher fullerenes and nanotubes samples of sufficient size and purity (and uniformity in the case of nanotubes) are just now beginning to become available, and more solid state NMR studies probing into the structure and properties of these materials should follow. In addition, solution ^3He NMR studies of the endohedral or *incar*-fullerenes $\text{He}@C_{60}$ and $\text{He}@C_{70}$, have shown how the helium atom can be used as a magnetic probe of the fullerene cage.³⁶ Variable temperature, solid state

Figure 9 Static room temperature ^{13}C (referenced to TMS), ^{39}K , ^{87}Rb , and ^{133}Cs (all referenced to the free alkali ions) spectra for a series of A_3C_{60} compounds. Features of interest are the presence of multiple tetrahedral environments for the larger Rb and Cs ions, the anisotropy indicative of the lack of C_{60} rotation with the Cs ions, and the absence of a large Knight shift between C_{60} and any of the alkali fullerides. (Reproduced by permission of the American Physical Society from Ref.³¹)

Figure 10 Knight shift (a) and T_1 (b) behavior as a function of temperature observed for $\text{Rb}_2\text{CsC}_{60}$, (T_c of about 30 K). All data is taken at a field strength of 8.8 T. The shifts for Rb in the figure are the center of mass of the two tetrahedral site resonances. The increasing chemical shift for Cs is believed to be due to a negative electron-nuclear hyperfine coupling. ((a) Reproduced by permission of the American Physical Society from Ref.³¹; and (b) Reproduced by permission of the American Physical Society from Ref.³⁷)

^3He NMR studies on these compounds should be of great interest.

1 INTRODUCTION

In general, the NMR properties of heterocyclic compounds are best understood by comparing them with ordinary organic compounds that do not contain heteroatoms. In this article the comparative aspects of heterocyclic compounds will be considered first, followed by a brief survey of the different classes of heterocyclic compounds, arranged according to the size and nature of the ring. The protons on the benzene ring experience a deshielding effect due to the aromatic ring current, which brings the chemical shift of the benzene protons to δ 7.24 ppm. The same ring current persists in the polyazabenzene as in benzene itself.

Since 1955 magnetic resonance spectra have been indispensable to any serious study of heterocyclic chemistry. Proton resonance spectra, for example, yield information regarding the number of hydrogen atoms present in the molecule as well as their chemical environment and their relative orientation in space (Table 1).

Table 1 Chemical Shifts in Proton Resonance Spectra of Various Heterocycles (δ , ppm)

Compound	Chemical shift at position		
	2	3	4

Imidazole	136.2	–	122.3	122.3	–

Compared with carbocyclic aromatic compounds the heteroaromatic compounds can basically be classified into two categories, those with π -deficient and those with π -excessive systems. This is experimentally demonstrated by the NMR chemical shifts of various nuclei. In the π -excessive systems the carbon atom resonances (Table 2) appear at much more shielded positions (δ 100–150 ppm) than do those of the carbons in π -deficient systems (δ 150–170 ppm).¹

The ¹⁵N chemical shifts of a number of heteroaromatic systems further demonstrate the electronic differences between π -deficient and π -excessive heteroaromatic compounds.² For example, the pyridine nitrogen (δ ¹⁵N 312 ppm) is much more deshielded than the nitrogen in pyrrole (δ ¹⁵N 149 ppm). The relative π -deficiency of a number of mono-, di-, and triazabenzene is reflected by the ¹⁵N chemical shifts given in Table 3. The most deshielded nitrogen of this series is pyridazine (δ ¹⁵N 400 ppm), whereas the most shielded nitrogens are found in pyrimidine (δ ¹⁵N 298 ppm). Thus the addition of nitrogen generally causes an increase in the π deficiency (pyrimidine being an apparent exception). In the π -excessive aza analogs of pyrrole, a similar trend is observed for the ¹⁵N chemical shifts. Introduction of additional nitrogen atoms causes deshielding and thus decreases the π excessiveness of the ring systems.

Nitrogen compounds with three different substituents exist in enantiomeric forms. Usually, however, these cannot be separated as the molecule undergoes rapid inversion, sometimes referred to as ‘umbrella-like’ inversion. The barriers to inversion can be increased when the nitrogen atom is in a three-, four-, or six-membered ring. For example, in *N*-chloroaziridine the inversion is so strongly hindered that it is

Table 3 Chemical Shifts of Nitrogen of Some Heteroaromatic Compounds

Imidazole	209

not possible to reach the coalescence temperature as decomposition occurs first ($T_c > 180^\circ\text{C}$).

2 THREE- AND FOUR-MEMBERED RINGS

The NMR spectra of three- and four-membered heterocycles display regularities of great value to structure determination. For protons on adjacent carbons the coupling constants J_{cis} seem to be always greater than J_{trans} . In three-membered rings J_{gem} is almost always smaller than J_{cis} and J_{trans} . The average values for aziridines are $J_{gem} = 1.4$, $J_{trans} = 3.3$, and $J_{cis} = 6.4$ Hz. The size of J_{gem} and of the vicinal C–H coupling constants seems to depend more on the number of nonbonding electron pairs at the heteroatom than on its electronegativity. In azetidine derivatives the proton-proton coupling constants J_{gem} on the carbons adjacent to nitrogen are 5–7.5 Hz, and J_{cis} is larger than J_{trans} (Table 4).

Nitrogen-15 NMR spectra of aziridines and azetidines have been measured. Relative to anhydrous ammonia the aziridine nitrogen absorbs at -8.5 ppm. *N*-Alkylation moves this shift to high frequency (downfield); for the *N*-Me derivative the signal is at 0.7 ppm, for *N*-CHMe₂ at 30.2 ppm, and for *N*-CMe₃ at 33.5 ppm. Aziridine ¹⁵N shifts parallel the ¹³C shifts—in a graph of ¹³C versus ¹⁵N shifts of aziridine derivatives the correlation coefficient was 0.953 . Azetidine ¹⁵N shifts are similar to those of the aziridines. Unsubstituted azetidine has its ¹⁵N resonance, relative to anhydrous ammonia, at 25.3 ppm and *N*-*t*-butylazetidine shows the signal at 52 ppm.

In contrast to most cyclic and acyclic amines, the bonding constraints of the aziridine ring have the effect of retarding nitrogen inversion rates to extents where they are measurable by NMR spectroscopy. In fact, dynamic NMR spectroscopy has enabled the relatively easy determination of rates of nitrogen inversion through the measurement of resonance coalescence temperatures. Electron delocalizing substituents on a small-ring nitrogen lower the inversion barrier by lowering the energy of the transitional, ‘flat’ geometry in which three substituents of the nitrogen are all in the same plane. Substituents bearing unshared electron pairs raise the inversion barrier to levels at which enantiomers can be isolated. Pure invertomers have been obtained of *N*-haloaziridines and *N*-alkoxyaziridines. Observed coalescence temperatures of aziridines range from below -160°C for *N*-acetylaziridine in vinyl chloride solution to above 145°C for *N*-ethylaziridine in D₂O.

N-inversion in azetidine and azetidin-2-one is rapid, even at -77 and -40°C , respectively. Again, halo substituents on nitrogen drastically slow the inversion rate, so that *N*-chloro-2-methylazetidine can be separated into two diastereomers. By

Table 5 Some Oxirane δ and J Values

Compound	$\delta^1\text{H}$ (ppm)	$\delta^{13}\text{C}$ (ppm)	J_{gem} (Hz)	J_{cis} (Hz)	J_{trans} (Hz)
Oxirane	2.54	39.7	—	4.45	3.1
Oxiranes	—	—	4.5–6.3	2.2–4.5	1.4–3.1

and large, the *N*-inversion barrier of azetidines is 38 kJ mol^{-1} lower than that of similarly substituted aziridines.

Chemical shifts and coupling constants for oxiranes are summarized in Table 5. The configurations of chiral thiiranes and thiirane 1-oxides can be determined by ¹H NMR experiments in chiral solvents such as (*R*)-(–)-1-phenyl-2,2,2-trifluoroethanol. The protons α to sulfur are usually shifted to higher frequency for the (*S*) configuration than for the (*R*) configuration, all shifts being relative to the shifts in carbon tetrachloride. The *cis* and *trans* isomers of 2,3-diphenylthiirane can be distinguished easily by the difference in ¹H NMR shifts caused by shielding of the protons in the *trans* isomer by a phenyl group; other *cis*–*trans* isomers may be differentiated by the fact that the *cis* coupling constant is generally larger than the *trans*.

Extensive NMR studies of azetidines support a conformationally mobile, nonplanar structure in which rapid *N*-inversion occurs. The magnitude of the vicinal coupling constant ($J_{cis} \approx 7.5$ Hz, $J_{trans} \approx 3.0$ Hz) is widely used in the assignment of stereochemistry. Azetidin-2-ones or β -lactams have been studied extensively because of their structural similarity with that of antibiotics—cephalosporins and penicillins. In general, $J(3,4)_{cis} \approx 5.0$ – 5.9 Hz, while $J(3,4)_{trans} \approx 2.2$ – 2.8 Hz; this provides a simple method for determining the relative stereochemistry of 3,4-disubstituted β -lactams.

Support for the planarity of the 1-azetidine ring comes from variable temperature NMR studies of 2-ethylthio-1-azetidine. Vicinal coupling constants in 2-alkoxy- and 2-ethylthio-1-azetidines are similar to those of analogous β -lactams, while geminal coupling constants in 3-substituted 1-azetidines are of greater magnitude [$J(4,4) \approx -10$ Hz].

The NMR technique has been of great value in assigning oxetane structures, particularly because the α -protons in oxetanes have much higher chemical shift values than in any other class of ethers. For the parent compound the chemical shifts are at 4.73 and 2.72 ppm in deuteriochloroform. ¹H NMR chemical shifts and coupling constants for a variety of thietane and thiete derivatives have been studied. In general, the α -protons of thietanes and their derivatives are deshielded relative to analogous derivatives with larger rings. Thus, the α -protons of thietane and thietane 1,1-dioxide absorb at δ 3.21 and 4.09 ppm, respectively, while the corresponding signals for the α -protons in thiolane and thiolane 1,1-dioxide are at δ 2.82 and 3.01 ppm, respectively. The α -proton chemical shifts of a series of cycloalkanes, oxacycloalkanes, azacycloalkanes, and cycloalkanones also show maximum deshielding at the four-membered ring.

An analysis of ¹³C NMR chemical shift data for thietanes and thietes reveals that thietane 1,1-dioxides, thiete 1,1-dioxides, and thietane sulfoximines show unusual α -carbon deshielding and β -carbon shielding when compared with other thiacycloalkane 1,1-dioxides and acyclic counterparts. This has been referred to as the ‘four-membered-ring sulfone effect’. Thus, the α -carbon shifts of thiolane and its 1-oxide

Table 4 Chemical Shifts of Proton and Carbon of Three-membered Heterocyclic Systems and their Coupling Constants

Compound	$\delta^1\text{H}$	J_{gem}	J_{cis}	J_{trans}	$\delta^{13}\text{C}$
Cyclopropane	0.22	–3–1	6–12	–4–8	–2.2
Aziridine	1.48	0.9–4	5–9	2–7	18–22
Oxirane	2.54	5–7	2–5	1–3	39.7
Thiirane	2.27	–14–1	6–7	5–6	18

and 1,1-dioxide are at 31.7, 54.3, and 51.1 ppm while the corresponding α -carbon shifts for thietane and its *S*-oxides are at 26.1, 52.7, and 65.6 ppm.

3 HETEROAROMATIC FIVE-MEMBERED RINGS

The ^1H NMR spectra of the parent heterocycles (Table 6) each consist of two multiplets, of which the one at higher frequency is assigned to the α -hydrogens. Apart from pyrrole, the chemical shifts for the β -protons increase with decreasing electronegativity of the heteroatom. In contrast, the chemical shifts of the α -protons do not display any obvious regularity, probably due to paramagnetic shielding contributions which will become more important with increasing availability of d orbitals. The chemical shift of the pyrrole N–H is solvent dependent.

Table 6 ^1H NMR Spectral Data for Five-Membered Heteroaromatics

Compound	H-2	H-3	<i>J</i> (2,3)	<i>J</i> (2,4)	<i>J</i> (2,5)	<i>J</i> (3,4)
Pyrrole	6.68	6.22	2.70	1.44	1.87	3.35
Furan	7.29	6.24	1.75	0.85	1.40	3.30
Thiophene	7.18	6.99	4.90	1.04	2.84	3.50
Selenophene	7.88	7.22	5.40	1.46	2.34	3.74
Tellurophene	8.87	7.78	6.70	1.30	2.60	4.00

4 SATURATED AND PARTIALLY UNSATURATED FIVE-MEMBERED RINGS

The α -hydrogen resonances for the fully saturated mono-cycles occur at higher frequencies than the β -hydrogen resonances. The chemical shifts of the β -hydrogens vary systematically with the electronegativity of the heteroatom, but the chemical shifts of the α -hydrogens do not (Table 7). The spectra of 2,5-dihydrofuran and 2,5-dihydrothiophene are simple, showing two singlets at 4.51 and 5.85 ppm for the dihydrofuran, and 3.66 and 5.79 ppm for the sulfur analog; the lack of coupling is in accord with an almost planar conformation.

Carbon-13 NMR on partially and fully saturated heterocycles is much more limited, and is summarized in Figure 1. As would be expected, the high frequency shift of the α -carbon atom decreases with decreasing electronegativity of the heteroatom in the sequence $\text{O} < \text{NH} < \text{S} < \text{CH}_2$.

5 HETEROAROMATIC SIX-MEMBERED RINGS

In the aza derivatives of the aromatic hydrocarbons the nitrogen atoms exert a strong deshielding influence on the

Table 7 ^1H NMR Spectral Data (ppm) for Saturated Five-Membered Rings with One Heteroatom

Compound	H-2	H-3
Pyrrolidine	2.77	1.63
Tetrahydrofuran	3.62	1.79
Tetrahydrothiophene	2.75	1.92
Tetrahydroselenophene	2.79	1.96
Tetrahydropyridine	3.10	2.03

Figure 1 ^{13}C NMR chemical shifts of some partially and fully saturated heterocycles

Figure 2 ^1H NMR chemical shifts of some heteroaromatic six-membered rings

α -hydrogen atoms, and a similar but smaller effect on the γ -hydrogens. The protons at the β positions in pyridine are in fact shifted slightly to lower frequencies than those of benzene (Figure 2). Further aza substitution produces similar effects, but strict additivity is not observed. For instance, two adjacent nitrogen atoms, as in pyridazine, exert a much larger deshielding effect on the α -protons than the sum of the α - and β -effects of a single nitrogen atom. Conversion of pyridine into the pyridinium cation causes a high-frequency shift of all the hydrogens, especially at the β and γ positions. The spectra of protonated polyaza heterocycles are frequently complicated by the occurrence of covalent hydration. This is more common with polycyclic systems, e.g. pteridine.

The extensive delocalization and aromatic character of pyridones, pyrones, etc., are shown by their chemical shift and coupling constant values (Figure 3). By contrast, pyrans and thiins show chemical shifts characteristic of alkenic systems (see below). For these and for rings containing only a single endocyclic double bond, ^1H NMR spectroscopy offers a most useful tool for structure determination. Solvent induced and lanthanide induced shifts are of great value in structure assignments in heterocyclic compounds, because cyclic nitrogen atoms, carbonyl groups, etc., undergo specific hydrogen bonding or coordination resulting in differential shifts of groups in different positions.

Figure 3 ^1H NMR chemical shifts and *J* values of some unsaturated six-membered rings

The normal pattern of coupling constants for aromatic six-membered rings is found in the heterocyclic aza systems, except that the *ortho* coupling to a proton α to a heterocyclic nitrogen is reduced from 7–8 to 4.5–6 Hz. The $J(2,3)$ value of pyrylium salts is still lower (about 3.5 Hz), but in pyridinium salts and pyridine *N*-oxide it is of intermediate value (about 6.5 Hz).

6 SATURATED AND PARTIALLY UNSATURATED SIX-MEMBERED RINGS

The chemical shifts of the α -, β - and γ -methylene carbon atoms of saturated six-membered ring systems are summarized in Table 8.

A nitrogen atom at X results in a variable high-frequency shift of the α -carbons, depending in its extent on what else is attached to the nitrogen. In piperidine the α -carbon signal is shifted by about 20 ppm to about δ 47.7 ppm, while in *N*-methylpiperidine it is at δ 56.7 ppm. Quaternization at nitrogen produces further effects similar to replacement of NH by an *N*-alkyl group, but simple protonation has only a small effect. *N*-Acylpiperidines show two distinct α -carbon atom signals because of restricted rotation about the amide bond. The chemical shift separation is about 6 ppm and the mean shift is close to that of the unsubstituted amine. The nitroso compound is similar, but the shift separation of the two α -carbons is somewhat greater (about 12 ppm). The signals of the β - and γ -carbon atoms of piperidines, *N*-acylpiperidines, and piperidinium salts are all to low frequency of the cyclohexane resonance, by 0–7 ppm.

7 SEVEN-MEMBERED AND LARGER RINGS

The NMR spectra of heterocyclic compounds with seven or more ring members are as diverse as the shape, size, and

degree of unsaturation of the compounds. NMR is perhaps the most important physical method for ascertaining the structure, especially the conformational, statics, and dynamics, of large heterocycles. Proton–proton coupling constants provide a wealth of data on the shape of the molecules, while chemical shift data, heteroatom–proton coupling constants, and heteronuclear spectra give information on the electronic structure.

Historically, ^1H NMR spectroscopy was vital in determining the structure of the first azepines and has since proved to be invaluable in the conformational analysis of azepines and their benzologues, and in determining ring inversion activation energies of these conformationally mobile ring systems. Chemical shifts for the azepine ring protons, as might be anticipated from their nonplanar, polyene character, lie in the vinyl proton region (δ 4.5–6.8 ppm). Long-range couplings are evident in methyl-substituted 3*H*-azepines. For example, there is allylic coupling ($J = 1$ Hz) between the 7-Me and H-6, and between the 5-Me and H-4 ($J = 1.5$ Hz) in 2-ethoxy-3,5,7-trimethyl-3*H*-azepine.

Ring inversion of the azepine ring between the two stable boat forms has been studied extensively by ^1H NMR spectra. Work on 2-anilino-3*H*-azepine showed a coalescence temperature of -55°C for the two conformers, and the barrier was calculated to be 42.7 kJ mol^{-1} . A feature of 1*H*-azepine chemistry that intrigued early researchers was the possibility of azepine-benzeneimine (or azanorcaradiene) valence isomerism akin to the oxepin-benzene oxide system. Variable temperature ^1H NMR evidence from simple azepines is overwhelmingly in favor of the azepine structure. For example, from low-temperature ^1H NMR studies on 1*H*-azepine it is concluded that the maximum amount of benzeneimine present at equilibrium must be $<1\%$.

The ^1H NMR spectrum of oxepane is not particularly informative and consists of two broad bands at δ 1.7 and 3.7 ppm due to coupling of the ring protons and to the electronegativity effect of the oxygen atom. The ^{13}C NMR chemical shifts have been studied over a range of temperatures but showed no evidence of splitting due to individual conformers even at -150°C , and suggested a low barrier to pseudorotation of about 17 kJ mol^{-1} . Benzannulation of the oxepane ring system leads to an increase in the barrier to ring inversion. Thus, variable temperature NMR spectra on 1,2,4,5-tetrahydro-3-benzoxepin suggested that a chair conformation was preferred with a barrier to ring inversion of about 39.7 kJ mol^{-1} .

NMR spectral studies have been used to investigate the oxepin-benzene oxide equilibrium. The ^1H NMR spectrum of oxepin at ambient temperature consisted of three multiplets of equal intensity centered at δ 6.1 (H- α), 5.7 (H- β), and 5.2 (H- γ) ppm due to the fast exchange process. At lower temperatures (-127°C , CF_3Br /pentane) the rate of isomerization decreased until individual signals for the oxepin tautomer were observed. The α -, β -, and γ -proton signals in oxepin are in typical chemical shift positions for a range of monocyclic substituted oxepins. The oxepin and benzene oxide valence isomers were also distinguishable in the low temperature ^{13}C NMR spectrum (-134°C , $\text{EtCl}/(\text{CD}_3)_2\text{CO}$). The spontaneous oxepin-benzene oxide isomerization proceeds in accord with the Woodward-Hoffmann rules of orbital symmetry control, and may thus be classified as an allowed thermal disrotatory electrocyclic reaction.

Table 8 ^{13}C NMR Chemical Shifts (δ , ppm) in Saturated Six-Membered Rings

X	2	3	4
CH ₂	27.7	27.7	27.7
S	29.3	28.2	26.9
S-O (ax)	45.1	15.5	24.7

O	68.0	26.6	23.6

Figure 4 Tautomeric equilibrium in organosulfur heterocycles

The ^1H NMR spectrum of thiepane was similar to that of oxepane and showed only two broad signals at δ 2.5–2.8 (4H; H-2, H-7) and 1.5–2.1 (8H; H-3, H-4, H-5, H-6) ppm. NMR spectral analysis of monocyclic thiepins indicates that the thiepin ring system in solution generally prefers a nonplanar (boat) conformation. The boat conformation would be anticipated for a thiepin ring having a minimal degree of conjugation. Clear evidence for bond alternation is obtained from the NMR spectrum of thiepins where the chemical shifts of thiepin ring protons correlate well with those of appropriate substituted ethylenes. The ring inversion process in thiepins has been studied by low temperature NMR spectroscopy and a barrier of about 26.8 kJ mol^{-1} has been determined for 3-methyl-6-isopropylthiepin 1,1-dioxide.

NMR spectral evidence for the presence of the valence tautomeric thianorcaradiene (benzene episulfide) form (analogous to the arene oxide tautomer of an oxepin) has yet to be observed. The latter negative evidence, however, does not exclude the possibility of a rapid thiepin-thianorcaradiene equilibration since the number of monocyclic thiepins which have to date been synthesized is very small, and since the examples examined by NMR probably owe their stability to the very low proportion of benzene episulfide tautomer present.

As in the oxepin-arene oxide system, the resonance effect will also influence the position of equilibrium in the analogous organosulfur series (Figure 4). Compound (2) is much more stable than thiepin (3) since formation of the thianorcaradiene tautomers would be much more difficult in (2) where a total loss of aromaticity would be involved.

1 INTRODUCTION

The phenomenon of hydrogen bonding has been recognized in chemistry for over 70 years and has been studied by a variety of physical methods including NMR, a technique that can provide insight into a number of features of the hydrogen bond. This article reviews some of the salient features of the hydrogen bond and shows the ways in which hydrogen bonding influences the principal NMR parameters, such as chemical shifts, scalar coupling constants, and relaxation times. We provide a number of examples to illustrate the ways in which the study of these and other NMR parameters can be used to clarify some aspects of the phenomenon of hydrogen bonding, to elucidate molecular structures, and to study various processes of physical, chemical, and biological interest.

2 NATURE OF THE HYDROGEN BOND

Molecules are held together by chemical bonds between pairs of constituent atoms and are usually of the order of $200\text{--}500\text{ kJ mol}^{-1}$ in energy. At the other extreme, molecules interact with each other via van der Waals forces, which are typically of the order of 5 kJ mol^{-1} for small atoms. Intermediate between these are various types of more specific interactions (e.g. electric dipole–dipole interactions) which tend to produce clusters of molecular aggregates, often termed molecular complexes. In 1920 Latimer and Rodebush explained many of the physical properties of water by advancing the idea of a specific interaction, beyond the normal covalent bonds, involving the hydrogen atoms in water. Subsequent research identified hydrogen bonds in a vast array of molecules and refined the concept of hydrogen bonding.

Probably the most succinct definition of the hydrogen bond is an operational one, given by Pimentel and McClellan¹ in their classic treatise on the subject: *A hydrogen bond exists between a functional group A–H and an atom or a group of atoms B in the same or a different molecule when (a) there is evidence of bond formation (association or chelation), and*

(b) there is evidence that this new bond linking A–H and B specifically involves the hydrogen atom already bonded to A. Criterion (b) differentiates hydrogen bonding from other types of association. Usually B is an electronegative atom or ion, such as oxygen, nitrogen or fluorine, and most often A is also such an electronegative atom. However, this definition of the hydrogen bond recognizes that interactions that might properly be termed hydrogen bonds can exist, for example, with certain C–H groups, such as that in chloroform, and that the hydrogen bond acceptor may be an electron-rich region in a molecule, such as π electrons in a double bond or an aromatic ring.

A hydrogen bond may be *intramolecular*, for example in salicylaldehyde (1), or *intermolecular*, as in the interaction between two methanol molecules (2) or between methanol and acetone (3). By the laws of mass action, the extent of intermolecular hydrogen bonding varies with the concentration of the constituents, whereas intramolecular hydrogen bonding may persist at low concentration in solution or in the gas phase at low pressure. Since the formation of a hydrogen bond is an exothermic reaction, the equilibrium constant for bond formation is expected to increase as the temperature decreases.

In addition to the thermodynamics, as expressed in the equilibrium constant, the *kinetics* of hydrogen bond making and breaking is a factor that is extremely important in NMR studies. Studies by ultrasonic absorption and dielectric relaxation have shown that many intermolecular hydrogen bonds in the liquid state are made and broken [equation (1)]

on a timescale (e.g. $\sim 10^{-5}$ s) that is fast relative to the difference in NMR frequencies between bonded and non-bonded forms. Thus, from the general theory of chemical exchange (see *Chemical Exchange Effects on Spectra*), we would expect in these cases to observe only an average NMR property (e.g. chemical shift or relaxation rate) for two or more molecular species in hydrogen bond equilibrium. Moreover, in solvents with exchangeable hydrogen atoms (such as water or alcohols), there may be an actual exchange of protons between different molecular species [equation (2)].

Note that the two processes shown in equations (1) and (2) are different, the first involving making and breaking of only hydrogen bonds, the latter resulting from breaking of covalent chemical bonds (and usually hydrogen bonds as well).

Figure 1 Variation of $R_{O\cdots O}$ and r_{O-H} for hydrogen bonds. (Reproduced by permission of Academic Press from Hibbert and Emsley²)

The impact of these processes on NMR spectra is profound, as we shall see. At the opposite extreme of exchange rates are solids and some stable structures in solution, such as biopolymers, where hydrogen bonds are quite long lived, and the NMR results reflect a slow exchange limit. We shall discuss examples.

Several techniques, including X ray and neutron diffraction, as well as solid state NMR, provide detailed information on the geometry of hydrogen bonds. In general, an $A-H\cdots B$ hydrogen bond is usually close to linear in systems where bond angle constraints are not violated. For some intramolecular hydrogen bonds [e.g. (1)], on the other hand, distinctly nonlinear hydrogen bonds are formed in accord with normal chemical bond angles. The $A\cdots B$ distance R_{AB} is often taken to be an approximate measure of hydrogen bond strength, with shorter distances corresponding to stronger hydrogen bonds. (As we point out in later sections, it is really the $H\cdots B$ distance that should be considered, and a departure from linearity in the hydrogen bond weakens the correlation between bond strength and R_{AB} .) Figure 1 shows that the $A-H$ chemical bond distance r_{AH} is affected little for very weak hydrogen bonds but is invariably elongated when a hydrogen bond of moderate strength is formed.² The distance r_{AH} is still significantly less than r_{HB} except for strong hydrogen bonds ($R_{AB} < \sim 245$ pm), where equal $A-H$ and $H\cdots B$ distances correspond to a symmetric hydrogen bond, found in only a few instances, such as $[F\cdots H\cdots F]^-$.

Theoretical explanations for the energetics of hydrogen bonds have been postulated for 40 years. Although they differ in detail, there seems to be general agreement that electrostatic attraction between $A-H$ and B accounts for almost all the energy of weak hydrogen bonds ($R_{AB} > \sim 260$ pm), but as this distance decreases, the repulsive force from electron energy exchange largely cancels the electrostatic attraction. Other forces, such as (i) polarization of B to create an induced dipole, (ii) dispersion forces (induced $A-H$ and B dipoles), and (iii) electron delocalization, must then contribute. Many current theoretical approaches use ab initio molecular orbital treatments of the entire system without partitioning the various contributions. One question which can be addressed by NMR is the extent to which electron delocalization (i.e. incipient covalent bond formation) actually occurs. We shall come back to this point.

3 EFFECT OF HYDROGEN BONDING ON ^1H CHEMICAL SHIFTS

The first reported effect of hydrogen bonding on a ^1H chemical shift came soon after the discovery of the ^1H chemical shift itself in ethanol. Packard and Arnold³ observed that the OH resonance, but not the CH_2 and CH_3 resonances, displayed a marked temperature dependence, an effect soon explained by Liddel and Ramsey⁴ as resulting from hydrogen bonding. In fact, as was shown later⁵ (Figure 2), the OH resonance of monomeric ethanol is at lower frequency (i.e. more shielded) than the CH_3 resonance, whereas in liquid ethanol at room temperature the OH resonance is about 5 ppm less shielded than that of the CH_3 protons. A vast amount of subsequent work has verified that hydrogen bonding to an electronegative atom always results in shifts to higher frequency for the $A-^1\text{H}$ resonance, with a magnitude as large as $\sim 10\text{--}15$ ppm. For some strong intramolecular hydrogen bonds in the enol form of β -diketones the observed chemical shifts are in the range of 20 ppm from the tetramethylsilane (TMS) reference. Likewise, in the solid state, carboxylic acids often have ^1H chemical shifts 12–14 ppm from TMS, but acid salts such as $\text{KHCH}_2(\text{CO}_2)_2$ show a chemical shift of about 19 ppm from the strong, symmetrical hydrogen bond.⁶

There is thought to be a qualitative correlation between the magnitude of the hydrogen bond shift and the strength of the hydrogen bond, but few hard thermodynamic data are available from solution studies. However, in the solid state the ^1H chemical shift correlates with R_{AB} , hence with the presumed strength of the hydrogen bond. For example, in maleic acid the ^1H signal from an intramolecularly bonded hydrogen is at 15.9 ppm, with $R_{O\cdots O} = 250.2$ pm, while the hydrogen in an intermolecular bond of 264.3 pm length has a chemical shift of 13.2 ppm.^{6,7} Moreover, an excellent linear correlation has been reported between the trace of the anisotropic ^1H chemical

Figure 2 Proton NMR spectrum of ethanol at 300 MHz (room temperature). The full spectrum is for undiluted ethanol, while the insets show the OH resonance of ethanol in CDCl_3 at 1.0 and 0.001 M, the latter representing almost entirely the ethanol monomer. Note that the OH resonance is a single line in the neat liquid and the 1.0 M solution because rapid proton exchange prevents observation of scalar coupling to the methylene protons, whereas a triplet structure is observed in the 0.001 M solution

shift in about 20 crystalline solids and the $H \cdots O$ distance as measured by X-ray and neutron diffraction.⁸ A slope of about -0.2 ppm per pm is found for r_{HO} from 130 to 190 pm.

The high frequency shift on hydrogen bonding is an important factor in interpreting ^1H NMR spectra, since OH and NH chemical shifts are often found to be solvent-dependent. In addition, the chemical shift of an OH or NH resonance can be of diagnostic value in structural elucidations when intramolecular hydrogen bonds are present. The shift to high frequency results from a decrease in diamagnetic shielding around the hydrogen nucleus, as demonstrated by molecular orbital calculations that show reduced electron density near the hydrogen. This redistribution of electrons in the $A \cdots H$ bond is probably brought about by repulsion from the nonbonding electrons in B .

A hydrogen bond to π electrons in aromatic rings leads to exactly the opposite observed shift, namely to low frequency. The reason is clear: the hydrogen atom bonds to the π -electron-rich face of the aromatic ring, where it is subject to a ring current effect that far outweighs any deshielding from the formation of the hydrogen bond itself. In this geometrical arrangement, then, the proton is subject to a net additional diamagnetic shielding, hence shifts to lower frequency.

NMR has been used to determine equilibrium constants and other thermodynamic properties for hydrogen-bonded systems. In most liquid phase systems there is rapid exchange between hydrogen-bonded and nonbonded molecular species, so that a single signal from the $A-H$ appears, as in the ethanol example. Then

$$\delta_{\text{obs}} = p_1\delta_1 + p_2\delta_2 + \cdots \quad (3)$$

where the p_i represent the fraction of $A-H$ in species i , with chemical shift δ_i . If there are thought to be only one or two hydrogen-bonded species, a number of data treatments can be used to permit the equilibrium constant(s) to be estimated from variation of δ_{obs} with concentration.

Two significant shortcomings to this determination by NMR are (i) the difficulty in obtaining an accurate measure of the chemical shift of the monomer and (ii) the problem of dealing with a multiparameter fit if several associated species are present. Reviews by Tucker and Lippert⁹ and Limbach¹⁰ give good summaries of the information that can be obtained and the limitations of these NMR methods. During the last 20 years there have been relatively few applications of NMR to determination of equilibria for hydrogen-bonded systems even though NMR techniques are now better able to provide data of adequate precision. Often it is preferable to utilize the NMR data only qualitatively and to derive equilibrium constants from other types of spectral data, such as infrared spectroscopy, where the time frame for exchange is such that bands for separate species can be identified.

In the situation described in equation (2), the hydrogen atom ionizes and exchanges rapidly with other species, such as water in an aqueous solution. When this condition obtains, quantitative evaluation of hydrogen bond equilibria generally becomes impossible.

If stable complexes are formed by hydrogen bonding (sometimes augmented by other factors, such as ionic or dispersion forces), the exchange rate may be sufficiently slow that separate signals can be observed for hydrogen-bonded and nonbonded species. A clear example is shown in Figure 3, where

Figure 3 Temperature dependence of the H-8 resonance (220 MHz) of guanosine 5'-phosphate in D_2O at a concentration of 0.59 M.¹¹ The weak peaks marked $\times$ in the spectrum at 25.5 °C are artifacts

a complex of guanosine 5'-phosphate is believed to consist of two tetramers stacked above each other with a sodium ion in the center (Figure 4).¹¹ Here the association is observed not by the hydrogen-bonded protons themselves (which have been exchanged with deuterium in the solvent in this example) but by other protons on the guanosine rings. The temperature-dependent equilibrium can be followed from the relative intensities of the monomer and structurally nonequivalent protons in the hydrogen-bonded complex.

In many biopolymers and oligomers the hydrogen-bonded protons themselves can be observed. For example, in tRNAs hydrogen bonds between the purine and pyrimidine bases are quite strong, and exchange with protons in the aqueous

Figure 4 Guanosine 5'-phosphate complex

Figure 5 Proton NMR spectrum of a self-complementary decadeoxynucleotide, $d(\text{GCATTAATGC})_2$, at 500 MHz in H_2O at 0.02 M¹²

solvent is suppressed. Figure 5 provides an illustration of a synthetic oligonucleotide in which the equilibrium so favors the hydrogen bonded form that no lines due to ‘free’ NHs are observed, while the bonded hydrogens show resonances at very high frequencies ($\sim 12\text{--}14$ ppm). Likewise in native proteins, amide hydrogens are found in the 8–10 ppm range because of strong hydrogen bonding.¹² These ^1H resonances can usually be observed in an H_2O solvent because the hydrogen bond slows down proton exchange rates. NMR has become an indispensable technique for studying rates of H–D exchange when the protein is deuterated in order to provide information on secondary and tertiary protein structure and to investigate the mechanism of protein folding.¹²

4 CHEMICAL SHIFTS OF OTHER NUCLEI

In the $A\text{--}H\cdots B$ system the chemical shifts of both A and B are found to change on hydrogen bond formation. The magnitude of shifts on hydrogen bonding for an ^{17}O in a carbonyl group that serves as a hydrogen bond acceptor (B) can be as large as 50–60 ppm to lower frequency, while an oxygen in a single bond in B (such as an ether) displays a low frequency shift of only a few parts per million.¹³ Oxygen-17 in the donor $A\text{--}H$, such as an alcohol or phenol, shifts $\sim 5\text{--}20$ ppm to higher frequency. Nitrogen-15 has been studied less extensively but shows somewhat similar behavior.^{9,14} In proteins, ab initio computations of ^{15}N chemical shifts indicate that typical hydrogen bonding interactions ($N\text{--}H\cdots O$) cause deshielding of the ^{15}N of about 13 ppm.¹⁵ Even ^{13}C in C=O groups is affected by hydrogen bonding, with shifts to high frequency of 2–40 ppm, depending partially on the strength of the hydrogen bond.¹⁶ However, other factors, such as nearby electric charges, can be equally significant in determining the chemical shift.¹⁷

While these hydrogen bond shifts are quite significant, they nevertheless represent only a relatively small fraction of the total chemical shift range for these nuclei, in contrast to the situation for ^1H chemical shifts, where the hydrogen bond effect may be the dominant factor in determining a chemical shift.

5 SCALAR COUPLING

Because one-bond $X\text{--}H$ coupling constants are known to depend on s character, and hence on hybridization of electrons

around X , it is expected that such couplings might be affected by hydrogen bonding with its accompanying redistribution of electron density in the $A\text{--}H$ bond. Only a few studies have been made of $^1J(X,H)$ for $X = ^{13}\text{C}$ and ^{15}N , where generally the coupling is found to increase slightly ($\sim 5\%$) on hydrogen bonding.^{14,18} Small changes in two- or three-bond couplings on hydrogen bonding have also been reported, but these primarily reflect conformational variations.

The question has been raised as to whether scalar coupling can be transmitted *through* a hydrogen bond. Such an effect would indicate that there is electron correlation, and hence covalent character, in the hydrogen bond. It is clear that such coupling could be observed only in a system such as an intramolecular hydrogen bond, where random exchange of group B does not occur through breaking of the hydrogen bond. Early attempts in our laboratory to demonstrate such coupling in intramolecular $\text{O--H}\cdots^{15}\text{N}$ systems provided ambiguous results because of tautomerism between $\text{O--H}\cdots^{15}\text{N}$ and $\text{O}\cdots\text{H--}^{15}\text{N}$ forms. However, recently several $^{113}\text{Cd}\text{--}^1\text{H}$ and $^{199}\text{Hg}\text{--}^1\text{H}$ scalar couplings, of 0.3–3.9 Hz, have been observed in metal-substituted rubredoxin (a small protein), each of which seems to be mediated via a hydrogen bond between a backbone amide proton and sulfur in a cysteine residue that is coordinated to the metal ion.^{19,20} Such three-bond couplings through the hydrogen bond provide strong evidence for covalent character in that bond.

The bifluoride ion HF_2^- has been of particular interest in theoretical investigations of hydrogen bonding, since it has a *symmetric* hydrogen bond, i.e. one in which the hydrogen is located halfway between the two electronegative centers. The NMR spectrum shows that the hydrogen is, in fact, equally coupled to the two ^{19}F nuclei, with $^1J(\text{F},\text{H}) = 120.5$ Hz, as compared with 476 Hz for HF. In a sense, this coupling goes ‘through’ the hydrogen bond, but it is a very unusual hydrogen bond.

6 RELAXATION EFFECTS

The theory of spin–lattice relaxation shows that the relaxation rate of a nuclear magnetic moment depends on the motions of the molecular system in which the nucleus resides (see **Relaxation: An Introduction**). For spin- $\frac{1}{2}$ nuclei the predominant relaxation mechanism usually depends on magnetic dipole–dipole interactions, mediated by random molecular motions described in terms of one or more correlation times, τ_c . Since intermolecular hydrogen bonding causes the formation of a complex larger than the nonbonded species, which both rotates and translates more slowly, both intramolecular and intermolecular correlation times are expected to change. Thus, the study of T_1 as a function of concentration, temperature, or change of conditions such as solvent can provide information on the extent of hydrogen bonding.

If hydrogen bonds are made and broken rapidly, relaxation rates are averaged, in the same manner as chemical shifts, and interpretation of the data often suffers from similar problems of multiparameter fits. In addition, the presence of more than one relaxation mechanism or correlation time further complicates data analysis. Only a few studies of complex systems have been carried out in which these parameters have

been controlled, for example by studying ^{13}C relaxation in molecules where dipolar interaction with protons dominates relaxation. Usually a full interpretation requires the use of ancillary data, such as infrared spectra or vapor pressure determinations.²¹

For systems in slow exchange, where only one hydrogen bonded species is present, relaxation measurements can often be analyzed to provide information on molecular size, structure, or conformation. For example, in 1-hydroxyfluorenone (4) the location of the hydrogen atom in an intramolecular hydrogen bond has been estimated from its effect on the relaxation of three nearby ^{13}C nuclei.²² Likewise, ^{13}C relaxation has been used to estimate the size and shape of molecular complexes such as that in Figure 4.²³

Extensive use has been made of ^1H NMR relaxation to explore hydrogen bonding and hydrogen exchange processes, especially in water. Because of the proximity of protons in adjacent molecules, intermolecular dipolar relaxation must be considered equally with intramolecular relaxation. Interpretation of the data is a rather complex process, discussed in detail by Hertz and Zeidler.²⁴

7 ISOTOPE EFFECTS RESULTING FROM HYDROGEN BONDS

Substitution of one isotope for another is known to affect the chemical shift of the substituted nucleus (primary isotope effect) and of nearby magnetic nuclei (secondary isotope effects). Most studies of the isotope effect (see *Isotope Effects on Chemical Shifts and Coupling Constants*) focus on the secondary isotope effect; indeed, in many instances the primary isotope effect is negligible. However, substitution of deuterium (or tritium) for hydrogen in a strong hydrogen bond causes a significant primary isotope effect, which provides information on the potential function for hydrogen bonding.

It is possible to define three types of hydrogen bond according to their strength—weak, strong, and very strong—and associated hydrogen bond length R_{AB} . As illustrated in Figure 6, the potential function is expected to vary as the two potential wells for the $A-H$ and $H\cdots B$ vibrational motions approach each other. For a weak hydrogen bond the occupied, zero-point level for the hydrogen stretching vibration in $A-H$ is well below the potential barrier, and that for deuterium in the isotopomer is, of course, still lower because of the mass effect. Thus, both H and D are essentially confined to the well as in an ordinary chemical bond, the existence of the hydrogen bond causes only a small perturbation, and the average r_{AH} is almost the same as r_{AD} , thereby leading to only a small primary isotope effect. However, as the hydrogen bond strengthens, the barrier eventually drops below the zero-point

Figure 6 Potential energy wells for hydrogen bonds, illustrating the zero-point vibrational levels for hydrogen and deuterium and indicating typical shortening of R_{AB} on formation of the hydrogen bond. (Reproduced by permission of Academic Press from Hibbert and Emsley²)

level, first just for hydrogen, then for both hydrogen and deuterium. The average r_{AH} and r_{AD} may then differ sufficiently to cause a measurable primary isotope effect. The limiting potential function is one with a single minimum, believed to be applicable in HF_2^- and several other very short hydrogen bonds, in which the isotope effect is again small. These expectations are in accord with experimental observations of proton chemical shifts and primary deuterium isotope effects in a range of hydrogen-bonded systems.² The isotope effect becomes large for moderate strength hydrogen bonds but is small for FHF^- . In fact, negative values have been found for the isotope effects on both ^2H and ^3H substitution in the strong hydrogen bonds of the hydrogen maleate and hydrogen phthalate anions.²⁵

Secondary isotope effects through two or more bonds are also useful in studying hydrogen bonds in a number of systems. One particularly interesting result occurs in (5), where the amino group rotation is slow enough to distinguish between the intramolecularly bonded and nonbonded hydrogens.²⁶ Deuterium isotope shifts ($^n\Delta$) for the three ^{13}C nuclei that are two or three bonds removed, as illustrated in (5), are approximately twice as large for substitution of the hydrogen-bonded proton as for substitution of the nonbonded hydrogen: $^2\Delta = 356$ versus 145 ppb; $^3\Delta = 148$ versus 74 ppb; $^3\Delta' = 136$ versus 64 ppb.

Useful information on hydrogen bonding can also be obtained from measurement of the equilibrium distribution of deuterium relative to hydrogen at the hydrogen bond site, as compared with the corresponding distribution in the solvent or some other standard, a quantity expressed as the isotope fractionation factor ϕ . A growing body of experimental evidence suggests that there is an inverse correlation between ϕ and the strength of the hydrogen bond. Although ϕ does not involve NMR parameters per se, NMR usually provides the best method for obtaining the necessary data. For rapidly exchanging hydrogen, the variation in chemical shift on isotopic substitution can be used to estimate ϕ ,² and for slow exchange the integrals of the separate signals usually give a precise measure of ϕ .² Proteins provide a particularly

interesting example, where ϕ has been found to vary over a very wide range (0.3–1.2) for different amino acid sites in staphylococcal nuclease.²⁷

8 MAGNETIC DIPOLE AND ELECTRIC QUADRUPOLE INTERACTIONS IN SOLIDS

The estimation of interatomic distances in solids by analysis of magnetic dipolar interactions has been applied to the study of hydrogen bond distances and geometry. Early NMR results on the bifluoride ion and later on other strong hydrogen bonds indicated that the proton is centrosymmetric, but generally the NMR data could not exclude rapid exchange between a double minimum potential with a small barrier. Solid state NMR has also been used to investigate the geometry of water of hydration in various crystals in order to study the effect of hydrogen bonding.²⁸

NMR has been used to investigate ferroelectric crystals, where, in some instances, the ferroelectric activity is believed to be related to changes in hydrogen position in a hydrogen bond: $\text{O}-\text{H}\cdots\text{O} \rightleftharpoons \text{O}\cdots\text{H}-\text{O}$. Deuteron NMR is particularly useful, since the nuclear quadrupole coupling constant (see *Deuterium NMR in Solids*) provides a sensitive measure of the asymmetry of the surrounding electric field. Above the ferroelectric transition temperature, where the deuterium is moving rapidly between two potential wells, e^2Qq decreases abruptly.²⁸

The deuterium quadrupole coupling constant, as determined from ^2H NMR or from pure nuclear quadrupole resonance, has been shown to vary significantly with hydrogen bond length. For example, excellent linear correlations have been found between e^2Qq for ^2H and $1/R^3$, where R is the $\text{D}\cdots\text{O}$ distance in bonds involving $\text{O}-\text{D}\cdots\text{O}$ or $\text{N}^+-\text{D}\cdots\text{O}$.²⁹ The correlations cover the range of weak hydrogen bonds, $R \approx 165\text{--}215$ pm, or R_{AB} (as defined previously) $\sim 260\text{--}310$ pm, with values of e^2Qq varying from 140 to 240 kHz.

1 INTRODUCTION

1.1 Definitions

Inclusion compounds belong to the class of guest-host materials where the host material provides a structural framework that contains void space that is occupied by a guest species. Such void space in inclusion compounds usually is classified as either a cage or a channel, although often the situation is more complex. In the case of well-defined cages, the materials are known as clathrates. In the case of layered materials, the void space is interlamellar and the materials are known as intercalation compounds. Some host frameworks are permanent, being composed of covalently bonded structural units such as the aluminosilicates known as zeolites and clays, but these will not be considered here. Instead, we will consider frameworks that can be classified as supramolecular, where the lattice is composed of building blocks that are assembled via van der Waals packing, hydrogen bonding or coordinate-covalent interactions. Examples of the first kind include inclusion compounds with cages or channels such as the cyclophosphazanes (Figure 1) and dibenzoylmethanates (Figure 2). The clathrate hydrates (Figure 3) and the β -quinols (Figure 4) are examples of hydrogen-bonded inclusion compounds, as are the channel inclusions of urea and thiourea. The coordination networks based on metal cyanides form an extremely versatile family of inclusion compounds with either cages or channels (see below). In many inclusion compounds more than a single type of bonding is present. For instance, in inclusions of Dianin's compound both van der Waals and hydrogen bonding are present, and the Werner clathrates pack according to van der Waals interactions, but since the building blocks bear a charge they require the presence of counterions (Figure 5). For a detailed presentation on structural and chemical aspects of inclusion compounds the series 'Comprehensive Supramolecular Chemistry'¹ (especially Volumes 6 and 7) will prove to be a valuable resource.

On the right is the parent metal dibenzoylmethanate host molecule where A stands for the axially coordinating vinylpyridine; both the axial ligand (substituted pyridines) and the metal species can be varied to give a large variety of host species. (D. V. Soldatov and J. A. Ripmeester, *Chem. Eur. J.*, 2001, **7**, 2979)

1.2 NMR Spectroscopy and Inclusion Compounds: A Historical Perspective

The class of inclusion compounds known as clathrates had been under study for about 150 years before the structural basis for these materials became apparent. H. M. Powell² coined the term clathrate when he recognized the structure of a β -quinol inclusion compound as being a guest species encaged by a host without any specific chemical interactions. Structural studies of this nature became possible because of the development of single crystal X-ray diffraction to the stage where it could be used to decipher in atomic detail the molecular entrapment of guest species within a host lattice.

It is interesting to note that the experimental basis for nuclear magnetic resonance spectroscopy is just slightly older than the official birth of clathrate science, as the first successful experiments were reported in 1946.³ In the middle 1960s, the group of C. A. MacDowell at the University of British Columbia was one of the first to apply the new methodology to inclusion compounds in a sustained manner. Urea channel inclusion compounds, clathrate hydrates and amine hydrates all were studied by moment analysis and/or relaxation methods. At the National Research Council of Canada, the Davidson group first used NMR spectroscopy in the middle sixties to

Figure 3 The polyhedral cages in the clathrate hydrate inclusions of structure I, structure II and structure H hydrates. The vertices represent the positions of the water molecule oxygens that are connected by hydrogen bonds. Also given are the space groups and the composition of the unit cells. S or S' stands for the small cages, L for large cage in each structure. The x^y descriptor denotes that a polyhedron consists of y polyhedra with x sides (Ref.⁶)

Figure 4 β -Quinol clathrate framework, showing the rings formed by 6 hydrogen bonded hydroquinone (1,4 benzenediol) host molecules (a), and a schematic representation of the mode of guest entrapment by the two independent but interpenetrating hydrogen bonded networks (b) of host molecules (T. C. W. Mak and B. R. F. Bracke, in 'Comprehensive Supramolecular Chemistry', eds J. L. Atwood, J. E. D. Davies, D. D. MacNicol, F. Vogtle, and J. M. Lehn, Elsevier: Oxford, 1996, Vol. 6, p. 23)

complement dielectric studies of guest and host dynamics of clathrate hydrates. The work by these pioneering groups has led to nearly 40 years during which NMR spectroscopy has become a tool of ever-increasing versatility in the unraveling of the complex interactions between guest and host in inclusion compounds. Over the years, the applications of NMR spectroscopy to the study of inclusion compounds have been reviewed a number of times.⁴⁻⁷ Below, we will address several classes of inclusion compounds in more detail. Many of the early approaches to solid state NMR spectroscopy are conveniently reviewed in the book by Fyfe.⁸

Figure 5 The empty host network of Dianin's compound clathrate (a). The top and bottom of the cage are formed by rings of 6 hydrogen-bonded host molecules, giving a double-sided 'egg-cup' structure. Stacks of 'egg-cups' give the double-sided cage held together by van der Waals interactions; (b) van der Waals' cross section through the double-sided cage; (c) the host molecule (From 'Inclusion Compounds', eds J. L. Atwood, J. E. D. Davies, and D. D. MacNicol, Academic Press, 1984, Vol. 2, p. 2, 16)

1.3 Problems Encountered in Inclusion Science

Two streams of thought contribute to modern concepts of inclusion chemistry. The first is classical and dates mainly from the statistical mechanical descriptions of inclusion compounds by van der Waals and Platteuw⁹ (see also Ref.¹⁰). The second derives from the development of supramolecular chemistry (chemistry beyond the molecule) as promoted by Lehn, Cram et al.,¹ where weak but specific and directional interactions play a more important role.

One of the main features of many inclusion compounds is that they are non-stoichiometric with a composition that depends on synthetic conditions. In such cases, the guest-host interactions are non-specific, and the empty host-lattice is unstable (it may be thermodynamically unstable, but persist because of slow kinetics). Such inclusion compounds exist as distinct phases only in the solid state, and arise when the components are brought together under the correct conditions of temperature (T) and pressure (P). They are described by the elegant 'solid-solution' formalism for clathrates.^{9,10}

A second class of materials arises when a guest molecule binds to a receptor molecule in solution, and the solution complex crystallizes under suitable conditions to give a solid inclusion compound. Materials that belong to this class include the cyclodextrins (See Vol. 2 in Ref.¹), native as well as modified (Figure 6), and the numerous versions of the versatile calixarenes.¹¹ Whether materials should be described as non-stoichiometric inclusions held together by non-specific interactions or as stoichiometric guest-host compounds with

Figure 6 Inclusion compound of β -cyclodextrin with polyethylene glycol (left) Water molecules in the structure have been omitted for clarity. An inclusion compound where the guest threads through a host molecule is known as a rotaxane. On the right a hexameric molecule of β -cyclodextrin is shown, with a representation of the anhydroglucose monomer unit in its center. (K. A. Udachin and J. A. Ripmeester, *J. Am. Chem. Soc.*, 2000, **122**, 12375)

specific binding often is not completely obvious, and it remains a key question in supramolecular science. In the former, only the simplest recognition principles apply (guest size, sometimes guest shape), in the latter some kind of specific (directional) interactions (H-bonding, π - π , C-H- π , etc.) should play a more important role, leading to the possibility of designing hosts for selective inclusion.

A very characteristic problem of many inclusion compounds is that often the guest and host sub-lattices have different symmetries. This introduces disorder, often dynamic, that involves especially the guest and sometimes the host. Thus, even though in many instances it is possible to obtain diffraction data, a good structural model requires a detailed understanding of the dynamic properties of the system. Thus, in a broad sense key issues involve the identification of new inclusion compounds, their structure, stoichiometry and dynamics, and the interplay amongst the latter. In well-developed areas of study such as the clathrate hydrates there also are compelling reasons to study kinetic processes such as formation and decomposition, thus posing new challenges for the study of transient structures, precursor phases, etc.

1.4 Scope

In this contribution we will outline the development of NMR spectroscopic applications to several classes of inclusion compounds, specifically, the clathrate hydrates, metal cyanides and calixarenes. A great variety of both organic and inorganic hosts and their guests are amenable to study by NMR

spectroscopic techniques, but it is not possible to cover the field in a comprehensive manner as it has now so widely diversified. However, it should become completely clear that NMR has played a leading role in providing answers to important questions in inclusion science, and with the advent of ever-new approaches it should continue to do so. The opportunities for complementarity between long-range order techniques such as diffraction and local order techniques such as NMR spectroscopy certainly have come to full realization in applications to inclusion science.

2 CLATHRATE HYDRATES

2.1 Introduction

The cage inclusion compounds (Figures 3 and 7) known as clathrate hydrates have been recognized as a rather special state of matter, and much effort has been devoted to their understanding especially because they are found in nature. Because of their ability to hold vast quantities of gas such as methane and other small molecules, they can be expected to have an effect on human welfare that still is not fully understood.¹²

Clathrate hydrates, probably are the best-understood inclusion compounds. They have been under study for ~ 200 years, and by NMR spectroscopy steadily for about 35 years.⁴⁻⁷ The field has benefited each time an innovation or new application in NMR spectroscopy has allowed the derivation of new types of information. Since clathrate hydrates also occur in natural and industrial settings there also is a considerable driving force not only for structural and compositional information,

Figure 7 (a) Mode of assembly of polyhedra for str. I hydrate. There are stacks of $5^{12}6^2$ cages along each of the cubic axes. The remaining space consists of the 5^{12} cages; (b) layer of face-sharing 5^{12} polyhedra, the basic structural unit in str. II and str. H hydrates. (c) layer of 5^{12} polyhedra from the side, with 5^{12} and the $5^{12}6^4$ polyhedra that arise between layers stacked in the ABCABC pattern for str. II. (d) layer of 5^{12} polyhedra from the side, with the $4^3 5^6 6^3$ and $5^{12}6^8$ polyhedra that arise between layers stacked in the ABAB pattern of str. H (J. A. Ripmeester, C. I. Ratcliffe, D. D. Klug, and J. S. Tse, *Ann. N. Y. Acad. Sci.*, 1994, **715**, 161)

but also for understanding formation and decomposition processes. Hence, significant challenges remain and there is much work to be done.

2.2 Early Studies: Dynamics and Hydrate Identification

Studies of dynamics in clathrate hydrates depended on the partial averaging of nuclear dipolar couplings in systems where the nucleus to be observed was of high natural abundance such as ^1H or ^{19}F . The mean square line widths (or second moments) of the resonance lines could be calculated exactly for static as well as dynamic models using the formalism of Van Vleck.³ The motional rates as well as activation energies could be obtained by measuring the spin-lattice relaxation times as a function of temperature. It was also discovered early on that contributions from the guest and host could be isolated by isotopic substitution. Not only can the contribution from either guest or host be made to disappear from the spectrum, but the substitution of H by D also leads to a significant reduction in the nuclear dipolar interactions because of the lower gyromagnetic ratio of D as compared to H, thus resulting in line shapes with better resolution.

Several lessons were learned early on. One was that quality control had to be carried out on synthetic hydrate samples, eg phase identification by powder XRD, in order to ensure that meaningful data were obtained. Further, it became apparent that special care had to be taken to exclude oxygen during hydrate synthesis, as oxygen is far more soluble in the solid clathrates than in the solution with which the hydrate is in contact. Oxygen is an excellent guest for the D cages (Figures 3 and 7, Table 1) that are common to all the clathrate hydrate structures shown. Most of the early relaxation studies and some lineshape studies were affected by the presence of paramagnetic oxygen, either causing enhanced spin-lattice relaxation or line broadening, especially at low temperatures because of Curie law behavior of the oxygen magnetic dipole.

The great mobility of polar guest molecules in the hydrate cages was already known from dielectric studies,⁴ and some models were presented that suggested hindrance to molecular motion arose from the interaction between molecular dipoles and electric fields in the hydrate cages. However, NMR experiments on non-polar molecules such as SF_6 showed that even these had a small but measurable barrier to rotation in the hydrate cages. In general, these results supported the ‘cage’

concept of clathrates as evident from the diffraction studies: a guest molecule physically entrapped in a host lattice with a great degree of reorientational freedom.

The main conclusions from early dynamics experiments can be summarized as follows. Reorientational processes can be studied quite easily with broadband NMR methods, however, as for dielectric experiments, the dynamic parameters always are dominated by the presence of distributed parameters.⁴ This also illustrates one of the essential differences between NMR and diffraction, and it becomes of particular importance for the hydrates. Although one could conclude from diffraction results that each cage has a definite point group symmetry (Table 1), the NMR experiments show that this in fact is not necessarily so. The hydrate frameworks suffer from the same disorder as observed in many forms of ice, that is, hydrogen atoms are disordered over two sites in each O–O bond. Diffraction shows this as the presence of two half-hydrogens in each bond, however, NMR shows that this is due to space averaging over many distinct cage configurations at temperatures where water motions are frozen in. Each cage configuration leads to somewhat different sets of potential minima for the guest and therefore, distinct dynamic properties. Formally, the distributed motional parameters can be accounted for by incorporating a distribution function (Cole–Davidson, log-gaussian, etc.) into the line-narrowing or relaxation descriptions. Mean activation energies for reorientation determined from both dielectric and NMR experiments range from $\sim 100\text{ J m}^{-1}$ to several kJ m^{-1} . For some simple guest molecules it was possible to distinguish several motional modes, such as reorientation of, as well as about, the polar axes of cyclobutanone and trifluoromethyl iodide guests. Quantum mechanical tunneling was seen to affect the line shapes of rotors with small moments of inertia such as CH_4 ⁸ and $-\text{CH}_3$. Here, barriers to internal rotation of the methyl groups were seen to have a component contributed by the cage that is also affected by the H-bond disorder and gives rise to distributions in the dynamic parameters.

It was also observed that the NMR spectrum of guests in previously unknown hydrates could be used to confirm the clathrate nature of the material. The line width of the NMR signal of the guest in the clathrate is unique in the sense that it is much narrower than that expected for the same guest molecules in its pure bulk solid phase, and much broader than that expected for a liquid. A number of new hydrate-forming guests were identified this way before further

Table 1 Hydrate cages, cage sizes and ^{129}Xe and $^{13}\text{CO}_2$ chemical shift data

^aEstimates for the cages roughly approximated as spheres from X-ray diffraction data.

^bIsotropic chemical shift.

^c $\Delta = \delta_{\text{iso}} - \delta_{zz}$ chemical shift anisotropy.

^dAsymmetry parameter $\eta = (\delta_{yy} - \delta_{xx})/(\delta_{\text{iso}} - \delta_{zz})$; the δ_{ii} are the chemical shift tensor elements; the ^{129}Xe shifts are referenced to xenon gas at zero pressure, the ^{13}C shifts to tetramethylsilane. The error estimates on both δ_{iso} and Δ^{Xe} are $\pm 1\text{ ppm}$, $\pm 2\text{ ppm}$ on Δ^{C} , ± 0.04 on η^{Xe} and ± 0.09 on η^{C} .

confirming the hydrate nature of the material by X-ray powder diffraction. In principle, the NMR signal even should reflect the cage symmetry, as the extent of motional averaging will depend quite markedly on the degree of asymmetry of the cage. If a guest forms more than one structure with guests in cages of different symmetries these can be distinguished quite readily.

The water molecules of the host lattice have been studied as well, and show dynamic properties closely related to those in ices.^{4,7} Reorientation is thought to occur by means of a Bjerrum defect mechanism. Considerable differences in dynamic rates and activation energies have been attributed to the nature of the guest molecule. Both the dipole moment and the ability to interact with the host lattice by transient hydrogen bond formation are seen to be important factors. In return, the dynamic state of the host lattice also has a profound effect on the dynamics of the guest molecules. Sufficiently rapid reorientation of the water molecules averages the different cage configurations mentioned above, so that the cages actually attain the high symmetries apparent from diffraction. Thus, the hydrates are excellent examples of frameworks for which both space and time averaging are observed.

As noted earlier, the use of D₂O for the host leads to magnetic isolation of the guest. Guests with small numbers of spins (2,3,4,6) grouped together all give fine structure in their spectra that are characteristic of the geometric arrangement of the spins and, sometimes, the chemical shift tensors.

2.3 Chemical Shift and Quadrupolar Tensors: Structure, Composition and Dynamics

The advent of Fourier transform spectroscopy and the availability of broad-banded high power amplifiers and decouplers in the middle 1970s led to a revolution in the way that solid state NMR was carried out.⁸ The first applications to clathrate hydrates date to ~1980 with a shift in emphasis on the nature of the information that became available.

One problem that is particular to clathrate hydrates is their non-stoichiometric nature. Therefore, in order for the complete structure to be defined, it is not only necessary to define the atomic positions of the guest and host, but also the cage occupancies. The van der Waals and Platteeuw⁹ elegant statistical thermodynamical model mentioned earlier, often referred to as the 'solid solution theory', can be used to account for the variable cage occupancies. The model assumes that there is a hypothetical empty clathrate lattice with a chemical potential $\Delta\mu$ greater than the ice lattice. The fractional occupancies of the small and large cages, θ_S and θ_L , respectively, are related to the minimum partial pressure P_D of the guest under which the hydrate is stable by Langmuir absorption-like expressions:

$$P_D = \frac{\theta_i}{(1 - \theta_i)C_i} \quad (1)$$

where C_i are Langmuir constants. Other assumptions are that the free energy difference is guest independent and that there are no guest-guest interactions. The chemical potential difference $\Delta\mu$ is then directly related to the absolute occupied cage fractions:

$$\Delta\mu = kT \sum_i v_i \ln(1 - \theta_i) \quad (2)$$

Here v_i is the number of cages of type i per water molecule. A converse of this is that for structure I hydrates the guest occupancy ratio determines directly the hydration number once $\Delta\mu$ is known. Although the theory had been used steadily with a great degree of success, it had never been tested at the molecular level. Testing of the theory for structure I hydrate where small guests occupy both kinds of cages requires a resolved signature from guests in the large T and small D cages (see Table 1, Figures 3 and 7). ¹²⁹Xe was chosen as the nuclide most likely to have the desired qualities: nuclear spin $I = 1/2$, a relatively large natural abundance ~26%, high gyromagnetic ratio (similar to ¹³C), and a large polarizable electron cloud that was hoped to be sensitive to cage size and/or shape.⁴⁻⁷ The results were extremely encouraging, showing a relationship between the isotropic chemical shift and cage size, and the anisotropic chemical shift and cage shape (Table 1). For a well-characterized xenon hydrate sample of known composition, the cage occupancy ratios led to the first completely experimentally determined value for $\Delta\mu$, $1297 \pm 110 \text{ Jm}^{-1}$. This is in remarkable agreement with values derived from fitting vapor pressure data.¹³

Since the pioneering experiments on ¹²⁹Xe, similar cage-dependent chemical shift effects have been found for most other spin 1/2 nuclides, the chemical shift difference for the two sites scaling roughly with the atomic weight of the nuclide under study.⁵⁻⁷ One of the more significant measurements was carried out on methane hydrate, where the ¹³C chemical shift difference of a few ppm required the application of magic angle spinning at low temperature in order to resolve the contributions, but without decomposing the sample.¹⁴ This laid the groundwork for using instrumental methods such as NMR to determine structure and composition of natural gas hydrates¹⁵ from resolved cage contributions and experimental occupancy ratios. The chemical shift pattern is diagnostic of the structure of the hydrate, making the technique of great analytical utility in general. ¹²⁹Xe chemical shift tensors are now available for all of the cages (except E) in structures I, II and H (Figure 8, Table 1)

Since guest molecules are quite mobile in the clathrate cages, the chemical shift tensors associated with spin 1/2 nuclei present in the guest molecules also are averaged by the guest motions. The extent of motional averaging is strongly dependent on the symmetry of the hydrate cage, and it is possible to calculate averaged tensors and associated lineshapes for different motional models. For hydrates containing CO₂, the isotropic chemical shift shows little dependence on the size of the cage, nevertheless, the chemical shift tensor is completely diagnostic of the asymmetry of the cage (Figure 9, Table 1).¹⁶

Another feature that has proved to be extremely useful is the ability to contrast signals arising from solids from those of liquids. Cross-polarization methods, where magnetization is first generated on a nucleus such as ¹H and then transferred to a second nucleus such as ¹³C or ¹²⁹Xe depends on the presence of dipolar coupling between these nuclei. Since these couplings are absent in liquids it is straightforward to distinguish guests trapped in hydrate cages from bulk liquid. Similarly, bulk xenon can be distinguished from xenon trapped in hydrate cages or xenon trapped next to water molecules.

The case for distinguishing hydrate cages based on guest dynamics extends to quadrupolar nuclei such as ²H. A number of examples have been given in which guests in the D and T

Figure 8 ^{129}Xe NMR spectra of str. I, II and H obtained with ^1H - ^{129}Xe cross-polarization at 77 K. For Str. II most large cages contain a second guest, and for str. H all large cages are occupied by a second guest species (Ref.⁶)

cages of structure I hydrate were distinguished and hydration numbers estimated from the occupancy ratios.⁵⁻⁷

In general, the chemical shift or quadrupolar tensors are more useful than dipolar couplings, as the latter require the evaluation of intra- and intermolecular lattice sums, whereas the former are essentially intramolecular in nature. Detailed models for the motion of the guest in the anisotropic cages are possible only when the cages take on their time-averaged symmetries.⁵⁻⁷ As discussed above, the disordered cage configurations that result when water molecule motions freeze in cause distributed guest dynamics, as illustrated for CO_2 hydrate.¹⁷

At this stage, NMR spectroscopy presents us with the tools to study hydrates that are able to provide structure-specific and quantitative site-specific information. The applications of the NMR techniques described above played the major role in the discovery of structure H hydrate¹⁸ and the subsequent exploration of suitable guests for this hydrate.⁷

2.4 The Study of Processes

One problem that has plagued NMR spectroscopy is its low sensitivity, thus often requiring significant data acquisition times in order to attain sufficient signal-to-noise ratios by signal averaging. The study of equilibrium properties such as structure and composition are well within the scope of NMR spectroscopy, as sufficient time can be taken to collect the

Figure 9 ^{13}C NMR powder pattern of CO_2 in hydrate polyhedra. (a, top spectrum) strI hydrate of $^{13}\text{CO}_2$ (a, lower spectrum) str. II hydrate of propane and $^{13}\text{CO}_2$ (line at ~ 17 ppm unresolved contributions from propane). Both patterns were determined using ^1H - ^{13}C cross-polarization. (b) str. H hydrate of neopentane and $^{13}\text{CO}_2$, determined by ^1H decoupled, single pulse technique. (sharp line in center is from excess gas and liquid, there also is a str. I hydrate impurity, as marked). In each cage, the pattern is determined by the dynamics of the CO_2 molecule in the cage, and illustrates the primary importance of cage symmetry. The 5^{12} cage in str. I and the $5^{12}6^4$ cage in str. II have cubic symmetry and hence give an isotropic spectrum, the other cages are asymmetric and give three structures have 5^{12} cages, although of different point group symmetries, and anisotropic spectra. It should also be noted that all hence they show different ^{13}C powder patterns (Ref.¹⁶)

data to give adequate signal-to-noise ratios. However, study of processes such as hydrate formation adds the need for time resolution. This means that the processes must be slow enough for the application of the standard spectroscopic techniques, or that new experimental approaches must be developed. In fact, both approaches have been explored for hydrates. The hope is that new information at the molecular level on the nucleation and kinetics of hydrate formation will lead to the development of useful models for the hydrate formation process. Specifically, this work will be of importance for the control of hydrate formation in pipelines, the possible recovery of gas from natural deposits, and industrial applications involving separation processes or gas storage.¹⁹

One approach has been to slow down the process of hydrate formation by going to low temperatures. In order to

eliminate mass transfer problems, it is necessary to prepare intimate amorphous mixtures of guest and host materials. Two methods are available for this: vapor co-deposition of water and the guest, and hyperquenching aqueous solutions of guest material by the extremely rapid cooling of micrometer-sized droplets.^{20,21} In both cases the product appears amorphous to X-ray diffraction. Annealing by progressively warming the samples at higher temperatures initiates a number of processes that eventually lead to crystalline clathrate hydrates. The characterization of the processes and products is a complex procedure, requiring input from a number of techniques, again used in a complementary fashion. The THF-water system was studied in this fashion. Differential scanning calorimetry was used to map out the temperature regions of reactivity, powder XRD was used to monitor the samples for crystalline products, and NMR and Raman spectroscopy were used to follow changes in local order. For the case in question THF- d_8 and ^2H NMR were used. As described above, first of all ^2H NMR is sensitive to the dynamic state of the guest, and some striking differences were noted between vapor-deposited and hyperquenched materials. However, additional information was needed, and a new experiment was developed to probe nearest neighbour interactions. The QEDOR experiment²² probes the guest-host interactions by monitoring the ^1H - ^2H dipolar couplings. In a crystalline clathrate, such interactions are maximized as each deuterated guest is completely enclosed in a H_2O host cage. If there is phase separation in which clusters of deuterated guest form, the ^1H - ^2H dipolar couplings become minimal. Probing of such interactions during an annealing cycle therefore allows conclusions to be drawn about the degree of dispersion of the guest in the host lattice. The main conclusions are that vapor-deposited THF water mixtures transform directly to the clathrate hydrate, whereas the hyperquenched material first phase-separates into crystalline THF and Ice Ic before reacting further to form the clathrate.

The second approach, that of increasing the sensitivity of the NMR experiment has also been realized. In many ways, ^{129}Xe NMR spectroscopy is the ideal technique for the study of hydrate formation, as the signals for the gas, gas dissolved in water, and gas in the two hydrate cages are well resolved.⁷ In principle it is possible to monitor the guest distribution quantitatively. However, the relaxation times of xenon are so long that time-dependent studies become impossible. The introduction of NMR techniques using hyperpolarized xenon have revolutionized Xe NMR spectroscopy, so that now it is indeed possible to carry out kinetic studies with hyperpolarized xenon.²³ Without going into details, the low sensitivity of traditional NMR spectroscopy arises from the small energy separation of the Zeeman levels in magnetic fields commonly available. The maximum signal that can be generated depends on the population difference between the levels, and at ordinary magnetic fields and temperatures this amounts to a few ppm. Hyperpolarized xenon is produced by spin exchange between the xenon nuclear states and rubidium that has polarized electron states produced by optical pumping, thus boosting the xenon population difference by a factor of 10^4 – 10^5 . The lifetime of the hyperpolarized state is long enough so that hydrate formation experiments can be carried out on the surface of ice (Figure 10). It is expected that these experiments will lead to new molecular models for hydrate formation.

Figure 10 Time-resolved ^{129}Xe NMR spectra following the reaction of hyperpolarized xenon with the surface of powdered ice. Each spectrum is a single scan. The gas line is near ~ 0 ppm, the large and small cages in str. I hydrate near ~ 150 and 240 ppm (I. L. Moudrakovski, A. A. Sanchez, C. I. Ratcliffe, and J. A. Ripmeester, *J. Phys. Chem. B*, 2001, **105**, 12 338)

2.5 NMR Imaging and Spatially Resolved Spectroscopy

NMR imaging (MRI), and the related techniques of spatially resolved spectroscopy, are well-established diagnostic tools in medicine, and are now finding an increasing number of applications to materials science. These techniques also are likely to play a role in the science of clathrate hydrates. The decomposition of mineral gas hydrates from natural hydrate deposits as well as the formation and decomposition of hydrate plugs in pipelines are obvious applications where space resolved and time resolved imaging can contribute a great deal of information. Some initial work has been carried out to identify the melting of ice inside hydrate-coated ice particles.²⁴ Currently the technique is limited to distinguishing solids from liquids, as, except in very special cases, the signal decay times are too short to observe solid hydrate directly.

3 METAL CYANIDE INCLUSION COMPOUNDS

Solid state NMR has played a crucial role in the study of metal-cyanide inclusion compounds, with regard to structural problems involving disorder and to the dynamics of both guest and host molecules. In these materials the frameworks are constructed from metal centers, typically Ni, Pd, Pt, Zn, Cd, Hg, Cu and Ag, connected by coordinating cyanides, CN, sometimes together with other ligands, particularly with amine groups.²⁵ Most often these involve square planar, octahedral, tetrahedral and occasionally 5-coordinated metal centers in a rich variety of structures, with cavities or channels occupied by guest molecules and molecular ions.

3.1 Host Frameworks

The NMR of metal nuclei, in particular ^{113}Cd but also $^{63,65}\text{Cu}$ and ^{67}Zn together with the ^{13}C and ^{15}N NMR of specifically labelled $^{13}\text{C}^{15}\text{N}$ has helped determine local structures in

numerous systems, many of which are disordered and therefore incompletely determined by diffraction methods. Furthermore X-ray diffraction has some difficulty in distinguishing directly between Cu and Zn atoms, and between C and N atoms, though sometimes it is possible to suggest an orientation for the CN based on the distances to the metal atoms. (In-depth reviews of this area and original literature citations may be found in Refs.^{5,7})

The most useful metal nucleus has been ^{113}Cd , which has spin 1/2, reasonable sensitivity and a sizeable chemical shift range. Furthermore, because of the presence of ^1H on many of the guest species it is often possible to carry out cross-polarisation and thus circumvent the often long T_1 of Cd itself. Early studies used CP/MAS spectra of several structurally ordered Hofmann-type and related inclusion compounds to determine the chemical shifts for Cd sites ranging from octahedral (Oh) CdN_6 or CdN_4O_2 to tetrahedral (Td) CdC_4 . The range now extends from around 150 ppm to 682 ppm (referenced to solid $\text{Cd}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$). The chemical shifts illustrate the great sensitivity of the Cd atom to its environment, even for complexes with closely related structures. The complementarity of X-ray and NMR structural information can be illustrated nicely by two examples of $\text{Cd}(\text{CN})_2$ inclusion compounds with different structures:

Pure $\text{Cd}(\text{CN})_2$ has a cubic structure consisting of two interpenetrating frameworks of Cd coordinated tetrahedrally by linking CN groups. Removal of one of the frameworks leaves voids which can be occupied by certain guest molecules such as neopentane and cyclohexane and hence form clathrates. Early X-ray powder work on $\text{Cd}(\text{CN})_2$ suggested it was ordered with CdC_4 and CdN_4 tetrahedral sites, whereas more recent single crystal work on the cyclohexane clathrate was unable to distinguish between C and N. ^{113}Cd MAS NMR of the cyclohexane clathrate $\text{Cd}(\text{CN})_2 \cdot \text{C}_6\text{H}_{12}$ (and of pure $\text{Cd}(\text{CN})_2$) unequivocally shows that there is static disorder

of the CN since there are 5 resonances from CdC_4 , CdC_3N , CdC_2N_2 , CdCN_3 and CdN_4 sites (Figure 11). This is quite distinct from an ordered structure which would have had only two equal lines from CdC_4 and CdN_4 , or a structure with dynamically disordered CN where all the Cd would be equivalent on time average and therefore give a single resonance. The low field line can be assigned to CdC_4 progressing to CdN_4 at high field, based on comparisons of shifts with ordered materials and on the following finer details of the NMR spectra: (a) J -coupling to ^{14}N , probably of the order of 137–190 Hz (and possibly some residual dipolar coupling due to effects of the ^{14}N quadrupolar interaction) causes the widths of the lines to increase with the number of attached N atoms. (b) The chemical shift anisotropy for the CdC_4 and CdN_4 centers is vanishingly small since they have close to perfect Td symmetry, resulting in lines with no spinning sidebands in the MAS spectra. (c) Chemical shift anisotropies for the much less symmetrical CdC_3N , CdC_2N_2 and CdCN_3 centers give rise to lines with several sidebands. The relative populations determined from line intensities of the resonances also indicate that the distribution of the 5 species is not purely statistical; CdC_2N_2 seems to be more favored and CdC_4 , CdN_4 least favored in these complexes.

Another interesting case is that of $\text{Cd}(\text{CN})_2 \cdot 2/3\text{H}_2\text{O} \cdot \text{Bu}^t\text{OH}$, which has a unique honeycomb-like framework structure, with the guest Bu^tOH inside linear channels. The X-ray structural data were consistent with five different space groups, from which one (Amm2) was tentatively chosen on the basis

Figure 11 ^{113}Cd NMR MAS spectrum of $\text{Cd}(\text{CN})_2 \cdot \text{C}_6\text{H}_{12}$ at 39.35 MHz. (a) CdC_4 ; (b) CdC_3N ; (c) CdC_2N_2 ; (d) CdCN_3 ; (e) CdN_4 . * = spinning sidebands. Inset: Cubic unit cell showing only the $\text{Cd}(\text{CN})_2$ framework, disordered C/N atoms shaded (S. Nishikiori, C. I. Ratcliffe, and J. A. Ripmeester, *Can. J. Chem.*, 1990, **68**, 2270)

Figure 12 ^{113}Cd NMR CP/MAS spectrum of $\text{Cd}(\text{CN})_2 \cdot 2/3\text{H}_2\text{O} \cdot \text{Bu}^t\text{OH}$ at 39.35 MHz. Spinning sideband manifolds are indicated for CdC_3N and CdC_2N_2 . The unit cell above shows the framework with the NMR ordering scheme. Filled circles = N, small open circles = C, hatched circles = disordered C, N, shaded circles = O, large open circles = Cd (S. Nishikiori, C. I. Ratcliffe, and J. A. Ripmeester, *J. Chem. Soc. Chem. Commun.*, 1991, 735)

that it gave the lowest R factor. This X-ray scheme is completely ordered with $\text{CdO}_2\text{C}_2\text{N}_2$ (Oh, with two H_2O), CdC_4 (Td) and CdN_4 (Td) centers. ^{113}Cd NMR shows isotropic CdC_4 and anisotropic CdC_3N and CdC_2N_2 resonances in a 1:2:1 ratio, as well as one Oh Cd line. From this it can be determined that the CN groups bridging Td Cd atoms are randomly disordered and the CN groups linked to the octahedral center are ordered to give CdO_2N_4 (Figure 12). Thus space group $\text{Amm}2$ is untenable and the choice is narrowed to three of the original five: Ammm , A2mm or A222 .

The picture which has emerged from the ^{113}Cd NMR results for $\text{Cd}-(\text{CN})-\text{Cd}$ linkages in these and other clathrates is that if the CN sits at an inversion center or symmetry axis which makes the two Cd crystallographically equivalent then the CN is statically disordered, 50% one way 50% the other, whereas CN linking inequivalent Cd can range from fully disordered 50:50 all the way through to fully ordered, 100:0. In some cases, provided the single crystal X-ray data is good enough, the atoms of ordered CN groups can be distinguished, but again the NMR can establish this unequivocally.

The use of doubly labelled cyanide, $^{13}\text{C}-^{15}\text{N}$, provides another route to structural information from NMR, which can be particularly useful when the properties of the metal nuclei involved make them less amenable to study than Cd, for example quadrupolar nuclei such as Cu or Zn. This isotopic enrichment has been used to great advantage to study $\text{NMe}_4\text{Cu}^+\text{Zn}(\text{CN})_4^-$ which has a framework structure very similar to that of the $\text{Cd}(\text{CN})_2$ -G clathrates with NMe_4^+ filling half of the cavities. The remaining cavities may be empty or filled with a neutral guest molecule. The cubic structure is retained for highly symmetrical guests such as CCl_4 , but is distorted to trigonal for CHBr_3 . For the empty clathrate an ordered structure with $\text{Cu}-\text{C}-\text{N}-\text{Zn}$ linkages was surmised from X-ray diffraction work, based on interatomic distances, even though Cu/Zn and C/N centers were indistinguishable. The observation of single isotropic lines for both $^{65,63}\text{Cu}$ and ^{67}Zn NMR (all nuclei with large quadrupole moments) showed that these centers have quadrupole coupling constants of zero and hence perfect tetrahedral symmetry and no disorder of the CN links. The orientation of the CN, however, could not be determined unequivocally until $^{13}\text{C}-^{15}\text{N}$ labelling was employed. Splittings in both the $^{65,63}\text{Cu}$ and ^{13}C MAS spectra from $J(^{13}\text{C}-^{65,63}\text{Cu})$ -coupling, confirm that the centers must be CuC_4 and ZnN_4 . From the static ^{13}C NMR spectra of the enriched sample it was possible to derive values for the $^{13}\text{C}-^{65,63}\text{Cu}$ and $^{13}\text{C}-^{15}\text{N}$ dipolar couplings and bond lengths, which indicate that the CN has a moderately large amplitude librational motion. This motion reduces the dipolar coupling and leads to a long apparent CN bond length of 1.2 Å, whereas it also leads to a rather short apparent CN bond length in the X-ray diffraction study (Figure 13).

There are Cu/Cd analogs of this structure and the carbon tetrachloride clathrate, $\text{NMe}_4\text{CuCd}(\text{CN})_4 \cdot \text{CCl}_4$ presents a few puzzles. It shows a single isotropic ^{63}Cu resonance, with no quadrupole coupling, at almost the same shift as the Cu/Zn framework, which is assigned to CuC_4 centers.⁸ However, although the ^{113}Cd spectrum shows an isotropic resonance from CdN_4 it also shows a second line with an axially symmetric chemical shift anisotropy (from a static spectrum),

Figure 13 $^{13}\text{C}-^{15}\text{N}$ labelled $\text{NMe}_4\text{CuZn}(\text{CN})_4$ ^{13}C CP NMR spectra at 45.26 MHz: (a) static, showing features due to ^{13}C shielding anisotropy, dipolar coupling to ^{15}N and dipolar and J coupling to $^{63,65}\text{Cu}$, any J anisotropy is indistinguishable from dipolar coupling; (b) MAS, showing quartets from $^{13}\text{C}-^{63,65}\text{Cu}$ J -coupling. The isolated sharp line is due to $\text{N}(\text{CH}_3)_4^+$. The inset shows the ordered structure with ZnN_4 and CuC_4 centers, N and Zn atoms in black (R. D. Curtis, C. I. Ratcliffe, and J. A. Ripmeester, *J. Chem. Soc. Chem. Commun.*, 1992, 1800)

with about 1/3 the intensity of the CdN_4 resonance, assignable to CdCN_3 . Since there are equal numbers of Cu and Cd this implies that about 1/4 of the Cu must be CuC_3N centers. The absence of a resonance for CuC_3N in the ^{63}Cu spectra can be explained as an effect of an extremely large quadrupole coupling constant arising from the loss of Td symmetry. The ^{13}C CP/MAS spectrum of the $^{13}\text{C}-^{15}\text{N}$ enriched material shows the same pattern of $J(^{13}\text{C}-^{65,63}\text{Cu})$ -coupled lines as in the Cu/Zn complex due to C in CuC_4 , but beneath this there is a broader and more complex pattern which is due to C atoms attached to CuC_3N and CdCN_3 centers. The CHBr_3 clathrate has a similar but distorted framework with trigonal symmetry, however, it also shows the 1:3 ratio of Cd resonances. Consequently, from the NMR and diffraction data it appears that the small fraction of CN which are reversed are randomly distributed throughout the lattice, and that this is a property of CN linkages between Td Cu and Cd centers. The $\text{NMe}_4\text{CuCd}(\text{CN})_4 \cdot \text{CHBr}_3$ clathrate also shows a single ^{63}Cu MAS NMR resonance, but in this case displaying second order quadrupolar effects, which must be from CuC_4 centers whose symmetry has been slightly reduced from perfect Td (Figure 14).

Figure 14 $\text{NMe}_4\text{CuCd}(\text{CN})_4 \cdot \text{CHBr}_3$. (a) ^{63}Cu NMR at 79.5 MHz, static and MAS showing 2nd order quadrupolar effects. (b) ^{113}Cd CP/MAS NMR at 66.55 MHz showing anisotropic CdN_3C and isotropic CdN_4 resonances. (Ref.⁷ and S. Nishikiori and C. I. Ratcliffe, unpublished results)

3.2 Guest Molecules

Guest species in metal cyanide inclusion compounds have largely been studied from the aspect of their dynamics and hence much use has been made of ^2H NMR and some ^1H T_1 as a function of temperature to determine the state of the motion and its activation energy, and how this relates to the symmetry and cavity shape and size. The effect of symmetry on the dynamics can be illustrated very elegantly by a comparison of cyclohexane C_6D_{12} in two complexes:

In $\text{Cd}(\text{mtn})\text{Ni}(\text{CN})_4 \cdot 1/2\text{C}_6\text{D}_{12}$ clathrate (mtn = *N*-methyl-1,3-diaminopropane) the cavity can be visualised as a square box and the cyclohexane fits into this with the 3-fold axis of its chair form along the 4-fold axis of the cavity. ^2H NMR (Figure 15) shows that n -fold (probably 12-fold) rotation about the cavity axis occurs at 77 K with an E_a estimated to be no more than 5.8 kJ mol^{-1} . This n -fold reorientation gives a characteristic lineshape consisting of broad and narrow doublets of equal intensity. This arises because the principal q_{zz} axis of the

Figure 15 ^2H NMR spectra at 27.63 MHz as a function of temperature. (a) $\text{Cd}(\text{mtn})\text{Ni}(\text{CN})_4 \cdot 1/2\text{C}_6\text{D}_{12}$: The 198 K spectrum shows rapid reorientation about the molecular 3-fold axis and crystal 4-fold axis. This motion is considerably slower at 77 K. At 397 K there is also rapid inversion. (b) $\text{Cd}(\text{CN})_2 \cdot 2\text{C}_6\text{D}_{12}$: The spectrum at 77 K is again characteristic of rapid reorientation about the molecular 3-fold axis, but the features are considerably broadened due to onset of new dynamics and CN disorder. There is rapid pseudo-isotropic motion by 148 K. The spectrum of the completely static C_6D_{12} in pure solid cyclohexane is shown at lower left for comparison (Ref.⁷)

quadrupolar coupling tensor of each axial deuteron is parallel to the rotation axis and therefore does not change orientation. The equatorial deuterons on the other hand do change tensor orientation and are therefore averaged. This motion is rapid by about 117 K. Between 230 and 390 K the ^2H lineshapes undergo changes due to the inversion of the molecule, for which an E_a of $44.7 \pm 1.0 \text{ kJ mol}^{-1}$ was determined by comparison of simulated and observed lineshapes. The inversion motion also causes a reduction of intensity and broadening of the ^{13}C CP/MAS NMR cyclohexane resonance in the region of room temperature, due to the dipolar fade-out which occurs when there is interference between the coherent averaging of the decoupling field and the incoherent averaging of the motion.

In the $\text{Cd}(\text{CN})_2 \cdot \text{C}_6\text{D}_{12}$ clathrate, whose cubic structure was described above, the cyclohexane sits within a cavity with tetrahedral symmetry. At 77 K the ^2H lineshapes⁶ (Figure 15) show that the cyclohexane is already undergoing rapid reorientation, most probably about its 3-fold axis, but the lineshape is already showing some effects of a second motion which is rapid and pseudo-isotropic by 140 K. Reorientation of the 3-fold molecular axis among just the four tetrahedral axes of the cavity will produce a pseudo-isotropic lineshape. Another point of interest is that the features of the lowest temperature

lineshapes lack clarity. This is probably due to the disorder in the CN orientations of the framework, which effectively means that there are very many slightly different cages which brings about a slight distribution in the widths of the averaged lineshapes. A similar effect was described above for the clathrate hydrates.

It can be seen that motion in both compounds is determined by reorientation about the molecular axis at low temperature but by the cavity shapes at higher temperature, and that the cyclohexane has much more freedom in the $\text{Cd}(\text{CN})_2$ clathrate.

4 CALIXARENE INCLUSION COMPOUNDS

Inclusion compounds formed with organic hosts form the third area of focus. The void space created by organic hosts may be intrinsic to the molecular structure (i.e., cavity-containing), or may be due to the long-range or collective assembly of host molecules in an ordered solid (i.e., cavity-and/or channel-forming). Examples of the former include cyclodextrins, crown ethers, Dianin's compound, while examples of the latter include tri-ortho-thymotides, cholic and deoxycholic acids and others.⁷ Some inclusion compounds, like the calixarenes, form both molecular and supramolecular cavities; and thus calixarenes provide an ideal system to illustrate the general application of solid-state NMR studies of organic inclusion compounds. Calixarenes are synthetically versatile giving great control over the cavity geometry, selectivity and solubility properties.^{11,26}

While calixarenes played a significant role in long-established phenolic polymers such as 'Bakelite', it was not until 1979 that X-ray diffraction established the nature of the molecular inclusion (Figure 16), and 1988 that the first solid-state NMR spectrum was collected.²⁷ The host is formed by four alkylphenols linked by methylene bridges to give a shallow cavity into which ions and small organic molecules are incorporated.

The ^{13}C CP-MAS NMR spectrum of *t*-butylcalix[4]arene•toluene at 20 °C (Figure 17b) shows two important structural features. First, each chemically-distinct carbon in the host *t*-butylphenol repeat unit has a single resonance, establishing the 4-fold (conical) symmetry of the structure. Second, the chemical shift value of the guest methyl carbon is deshielded relative to that in pure toluene solution. This complexation-induced chemical shift arises from the electron density of the host aromatic rings, and its value generally indicates the orientation of the guest molecule in the host cavity.^{27,28} Thus in the case of toluene, the guest methyl group is situated

Figure 16 Guest-host unit of the 1:1 inclusion compound of *p*-*tert*-butylcalix[4]arene with toluene, from the crystal structure determination (a); chemical structure of host unit (b)

Figure 17 ^{13}C CP-MAS NMR spectra of the inclusion compound of *p*-*tert*-butylcalix[4]arene with toluene: (a) low temperature, (b) room temperature, (c) after conversion to 2:1 compound at ~150 °C

deep in the host cavity. ^{13}C CP-MAS NMR spectroscopy has been used as a screening technique for both symmetry and orientation structural features with variations in the guest, and also in conjunction with complementary techniques such as TGA.^{28,29}

Upon lowering the temperature below a phase transition at -20°C , the signals in the ^{13}C CP-MAS NMR spectrum of *t*-butylcalix[4]arene•toluene increase in multiplicity, indicating that the symmetry is lowered (Figure 17a). Furthermore, an increase in temperature causes a structural change as 50% of the toluene molecules leave the solid; this too is reflected in changes in the ^{13}C CP-MAS NMR spectrum (Figure 17c).

With modification of the ^{13}C CP-MAS technique to allow the magnetization to be dephased briefly by ^1H - ^{13}C dipolar interactions prior to acquisition under ^1H decoupling, the signals due to carbon nuclei with strong dipolar couplings to protons (rigidly held in the crystal lattice) disappear, while those of carbon nuclei with weaker couplings (quaternary carbons and proton-bearing carbons involved in molecular motion) persist. The disappearance of the toluene C_4 signal indicates that the C-H bond lies on an axis of molecular reorientation (Figure 17b).

^2H NMR is widely used to describe the motion of guest molecules in clathrates and inclusion compounds as temperature is varied. The toluene guest molecule re-orientates in the *t*-butylcalix[4]arene cavity as a function of the cavity symmetry. Below -20°C , the ^2H NMR lineshapes indicate a 2-fold reorientation ($=180^\circ$ jump) about the guest symmetry axis, whereas at higher temperatures, the lineshape indicates 4-fold

reorientation ($=90^\circ$ jump). Thus ^2H NMR spectra indicate that the local cavity has 2-fold symmetry at low temperatures, and 4-fold symmetry at high temperatures. Such information has been invaluable in resolving ambiguous diffraction data for the low-symmetry structure.²⁹ In general, inclusion compounds often possess significant molecular motion, and ^2H NMR is a unique tool to describe such 'soft' materials.

The structure and dynamics of inclusion compounds may also be investigated further with the use of ^{129}Xe NMR of inclusion compounds formed with xenon as guest, with t-butylcalix[4]arene•Xe as an example.²⁹ Xenon, with its large chemical shift range, is very sensitive to its local chemical environment, giving insight into symmetry and motion. The implementation of hyper-polarized ^{129}Xe NMR holds great promise as a technique to investigate organic inclusion compounds.

The relatively small size of the calixarene host lends itself to the application of NMR distance techniques based on the re-introduction of the dipolar interaction between two (or more) nuclei. A ^{19}F -containing guest has been used to determine the distance between host ^{13}C and the guest ^{19}F nuclei using REDOR.³⁰ However, such distance determinations are complicated by the need to describe any molecular motion prior to fitting the REDOR dephasing curves.

As the need for structural and dynamic information of inclusion compounds increases, the application of more complex NMR experiments such as REDOR and those using hyper-polarized ^{129}Xe will complement the wealth of information gained from the more routine ^{13}C CP-MAS NMR techniques.

Biographical Sketches

John A. Ripmeester, b 1944. B.Sc., 1965, Ph.D., 1970, University of British Columbia. Trained in solid state NMR in graduate school and during post-doctoral work (University of Illinois, Urbana), he joined the National Research Council of Canada in 1972 to study clathrate hydrate inclusions. Currently he leads a multidisciplinary group at NRC that synthesizes and characterizes functional materials. Approx. 370 papers; recent emphasis mainly on the characterization of supramolecular and mesoporous materials, with a heavy NMR component; 4 patents. Research interests: characterizing complex interactions in the solid state.

Christopher Ian Ratcliffe, *b* 1951. B.Sc., 1972, Ph.D., 1975, University of Durham, UK. Trained in solid state NMR during post-doctoral work (University of British Columbia), and as a Research Associate at the National Research Council of Canada. He joined NRC in 1982 where he is currently a Senior Research Officer in the Functional Materials Program. Approx. 170 papers. Current research focus: clusters and wires in zeolites and mesoporous materials, metal-silicon and related clathrates, applications of ^{129}Xe NMR, order/disorder and dynamics in solids.

Eric B. Brouwer, *b* 1967. B.Sc., 1990 Queen's University, M.Sc. 1992 University of British Columbia, Ph.D., 1996, Carleton University. Post-doctoral work with R. K. Harris at University of Durham in solid-state NMR. He is currently employed as a Research Scientist at i-STAT Corporation. Approx. 25 papers in supramolecular chemistry and NMR spectroscopy.

Indirect Coupling: Theory and Applications in Organic Chemistry

1 INTRODUCTION

Nuclear spin–spin coupling theory has been the subject of several reviews^{1–4} and it has been an annual topic in the Royal Society of Chemistry Reports since 1972.^{5,6} In recent years there has been a renewed interest in the factors controlling heteronuclear spin–spin coupling constants. This is partially attributable to the emergence of multiple pulse techniques for spectral editing as these have produced a wealth of new data.

Like many other topics in NMR an exhaustive review of indirect nuclear spin–spin coupling theory would not be possible within the limitations of this review. Moreover, various aspects of J coupling will appear in other chapters of this monograph. Thus, the scope of this chapter is narrowed to reflect the author's interests in this topic for the past 30 years and to bring some coherence to this material. The coverage of the literature is fairly complete up until the early 1970s. It was at about this time that the FPT-INDO method [finite perturbation theory in the intermediate neglect of differential overlap approximation of self-consistent field molecular orbital (SCF-MO) theory] became generally available and was applied to an enormous number of problems.⁷ In recent years high quality ab initio computations have appeared. These use large basis sets and include extensive correlation corrections applied to both Fermi contact and noncontact mechanisms.^{8–15}

The spin–spin coupling phenomenon quickly emerged as a powerful tool for structural and conformational studies, in part, because of the general applicability of semiempirical methods in reproducing conformational and substituent trends. This is in marked contrast with chemical shielding where the data are even more abundant but semiempirical methods have not been as useful. The first part of this chapter will describe the observation and early interpretation of the spin–spin coupling phenomenon. The second part will present an overview of theoretical descriptions as expressed in density matrix notation and exemplified by semiempirical methods. The final section applies the theory to some organic structural aspects of J coupling, again emphasizing topics of interest to the author.

2 OBSERVATIONS AND EARLY INTERPRETATIONS

The early work in the observation of spin–spin coupling will be described elsewhere in this article and will only be described briefly here. In 1950 the application of spin echo methods to ethanol by Hahn¹⁶ showed ‘slow beats’ in the echo. These were later shown to arise from nuclear spin–spin coupling. Using slow passage conditions, the fine structure in the ¹²¹Sb resonance of a solution of NaSbF₆, which was observed by Proctor and Yu,¹⁷ was thought to arise from the magnetic dipole interaction of the Sb nucleus with the surrounding F nuclei. Gutowsky and McCall¹⁸ also observed fine structure in ³¹P and ¹⁹F spectra. In 1951 there were several other papers on this topic^{19,20} and it was soon concluded that the interaction is independent of the external field but that it does depend on the product of the nuclear spin vectors,^{21–23}

$$\Delta E_{NN'} = h J_{NN'} \mathbf{I}_N \cdot \mathbf{I}_{N'} \quad (1)$$

where $J_{NN'}$ is the nuclear spin–spin coupling constant in hertz. The physical basis for these splittings was disputed until the appearance of papers by Ramsey and Purcell²⁴ and Ramsey.²⁵ They concluded that the interaction arises from ‘the magnetic interaction between each nucleus and the electron spin of its own atom together with the exchange coupling of the electron spin with each other’. In the absence of a magnetic field the spin–spin coupling constant for H₂ is simply the energy difference in hertz between *ortho*- and *para*-hydrogen, e.g. in the absence of a magnetic field it is the difference between the triplet and singlet nuclear spin levels. This is depicted in Figure 1 for a pair of equivalent spin- $\frac{1}{2}$ nuclei. The nuclear Zeeman levels are plotted as a function of the magnetic induction B_0 . The J coupling is taken to be of positive sign if the nuclear spin singlet energy is lower than the triplet energy. This is the case for H₂ because the Fermi contact mechanism (which is dominant) favors the antiparallel arrangement of electron and nuclear spins.

In his 1953 paper Ramsey developed a general formulation for nuclear spin–spin coupling. Equation (1) implies that coupling constant terms will occur in first order perturbation theory if the operators contain the product $\mathbf{I}_N \cdot \mathbf{I}_{N'}$, e.g. the one-electron or orbital diamagnetic term. Contributions will also arise in second order perturbation theory as products of operators ($A_N \cdot \mathbf{I}_N$ and $A_{N'} \cdot \mathbf{I}_{N'}$) containing the two nuclear spins. Ramsey identified three interaction terms of this form, those involving the electron orbital motion with the nuclear spin, the dipolar term involving the electronic spins and the nuclear spins, and the Fermi contact interaction associated with the electronic and the nuclear spins. Ramsey's expression for the (isotropic) Fermi contact term, which is of primary interest here, in Gaussian units is

$$J_{NN'} = -(2/3h) \left(16\pi\beta \frac{\hbar}{3} \right)^2 \gamma_N \gamma_{N'} \sum_{\kappa} ({}^3E_{\kappa} - {}^1E_0)^{-1} \times \left\langle 0 \left| \sum_j \delta(r_{jN}) S_j \right| \kappa \right\rangle \left\langle \kappa \left| \sum_k \delta(r_{kN'}) S_k \right| 0 \right\rangle \quad (2)$$

where $J_{NN'}$ denotes the isotropic coupling between nuclei N and N' having magnetogyric ratios γ_N and $\gamma_{N'}$, respectively. The first summation is over all triplets κ . In the Fermi contact

Figure 1 Energy level diagram for two equivalent spin- $\frac{1}{2}$ nuclei plotted as a function of the magnetic induction B_0 . The coupling constant J is the separation between the nuclear spin singlet and the nuclear spin triplet

operators $\delta(r_{jN})$, for example, denotes the Dirac delta function for electron j at nucleus N , S_j is the electron spin operator for the j th electron, and the summation is taken over all electrons j . Matrix elements connect the singlet states $\langle 0|$ having energy 1E_0 and triplet states $|\kappa\rangle$ having energies $^3E_\kappa$. Equation (2) is the starting point for most discussions of Fermi contact coupling. Ramsey also recognized the tensor nature of the J coupling but for the HD molecule only reported numerical estimates of the *isotropic* terms. Based on the James and Coolidge wavefunction, a value of 40 Hz for the Fermi contact term is in reasonable accord with the experimental value of 42.7 ± 0.7 Hz.²⁶ This also supported arguments for small contributions from noncontact mechanisms. Following speculation that the H–D spin–spin coupling constant had a negative sign,²⁷ Code and Ramsey used molecular beam methods to demonstrate²⁸ that the sign was indeed positive.

Ramsey also made the interesting observation that as the atoms of HD are pulled apart, the denominator in equation (2) approaches zero, a situation in which perturbation theory would not be applicable. Because of a possible relationship to long-range coupling, the dependence of the H–H nuclear spin–spin coupling on $r_{HH'}$ was examined²⁹ using a variational method with Heitler–London wavefunctions including both the electron and nuclear spins. In the dissociation limit the splitting is the electron–nuclear hyperfine coupling. The total electronic spin S cannot be a good quantum number as the molecule dissociates as this would have the contradiction of nuclear spin–spin coupling being nonzero at infinite separation. In the simple Heitler–London picture for which the singlet and triplet energies are asymptotic as $R \rightarrow \infty$, the four

basic product electron spin functions necessarily assume equal weights corresponding to two uncorrelated spins. Had effects as small as the indirect nuclear spin–spin coupling been of interest, these would have been implicit in the detailed work of the Wisconsin group on the H_2 hyperfine splitting.³⁰ The previous reviews^{1–6} should be consulted for references to the many papers concerned with calculation of the HD coupling constant.

Before looking at specific molecular formulations, it will be convenient in the next section to transcribe the various expressions for (Fermi contact) nuclear spin–spin coupling constants into density matrix notation. These techniques will then be used in Sections 3.2–3.4 to discuss the specific quantum mechanical formulations.

3 THEORETICAL FORMULATIONS FOR NUCLEAR SPIN–SPIN COUPLING

3.1 Density Matrix Notation

The density matrix notation adopted here follows that introduced by McWeeny and co-workers.^{31,32} This formalism was used extensively in these laboratories to investigate nuclear spin–spin coupling and a number of other types of NMR parameters. The one-electron *transition density matrix* associated with states Ψ_κ and Ψ_λ is given by

$$\rho_1(\kappa\lambda | 1; 1') = N \int \Psi_\kappa(1, 2, 3, \dots, N) \Psi_\lambda^* \times \Psi_\lambda(1', 2, 3, \dots, N) dr_2 dr_3 \dots dr_N \quad (3)$$

where N is the number of electrons and the integrations are to be taken over the space and spin coordinates r_i of all but one electron. It is sometimes convenient to write the one-electron density matrix in terms of spinless components,

$$\rho_1(\kappa\lambda | 1; 1') = P_1(\kappa\lambda | 1; 1') \alpha(1) \alpha^*(1') + P_1\kappa\lambda | 1; 1') \beta(1) \beta^*(1') \quad (4)$$

from which it follows that for a given state ($\kappa = \lambda$) the diagonal element denotes the probability of finding an electron in volume element at point 1. *Transition spin densities* occur when spin operators are involved and these can be written in terms of the spinless components,

$$Q_1(\kappa\lambda | 1; 1') = P_1(\kappa\lambda | 1; 1') - P_1(\kappa\lambda | 1; 1') \quad (5)$$

For a given state ($\kappa = \lambda$) $Q_1(\kappa\kappa|1;1)$ is just a *spin density* for which integration over all space gives the number of unpaired spins.

From equations (2)–(5) the expression for the Fermi contact (FC) contribution to the isotropic spin–spin coupling is

$$J_{NN'} = -(2h)^{-1} (16\pi\beta\hbar/3)^2 \gamma_N \gamma_{N'} \sum_{\kappa} ({}^3E_\kappa - {}^1E_0)^{-1} \times Q_1(0\kappa_0 | 1_N; 1_N) Q_1(0\kappa_0 | 1_{N'}; 1_{N'}) \quad (6)$$

where $Q_1(0\kappa_0|1_N;1_N)$, for example, denotes the transition spin density evaluated at the position of nucleus N. The advantages of using density matrix notation rather than the integrals in equation (2) are the removal of the spin operators and the ease of writing general density matrix expressions. General density matrix expressions analogous to equation (6) can also easily be written for coupling constant contributions associated with the spin dipolar (SD), and orbital paramagnetic (OP) contributions, as well as the various cross terms.^{33,34}

The initial theoretical work on J coupling invoked the so called ‘average energy approximation’ to simplify the second order expressions. This procedure invokes closure in the second order sum and replaces the excitation energies by an average value ΔE . Although it has long been clear that this procedure is not an approximation in the usual sense of the word,^{35,36} it has led to some very important relationships between J couplings and molecular structures as well as some useful qualitative insights that have permitted correlations of many structural features. The ‘average energy approximation’ was particularly appealing in its very simple relationship to the electron correlation features in n -particle systems.^{32,37,38} In density matrix notation the FC contribution to the spin–spin coupling between nuclei N and N’ at this level of theory is given by³²

$$J_{NN'} = -(3h\Delta E)^{-1}(16\pi\beta\hbar/3)^2\gamma_N\gamma_{N'}Q_c(1_N, 2_{N'}; 1_N, 2_{N'}) \quad (7)$$

where $Q_c(1_N, 2_{N'}; 1_N, 2_{N'})$ denotes a two-electron spin density (or spin coupling matrix) evaluated at the positions of the coupled nuclei, and ΔE is an ‘average excitation energy’. The usual state labels of density matrix notation are not used here because only the ground state wavefunction is involved. The two-electron spin density matrix is related to the two-electron spinless components of the density matrix,

$$Q_c(1, 2; 1', 2') = 3[P_2(1, 2; 1', 2')^{\alpha\alpha\alpha\alpha} - P_2(1, 2; 1', 2')^{\alpha\beta\alpha\beta}] \quad (8)$$

where the first term on the right denotes the simultaneous probability of finding the two electrons with α spin in differential volume elements at points 1 and 2, and the second term denotes the corresponding probability for electrons of opposite spin. We now look at some important implications of these relationships. The spinless components in equation (8) are related to the one-particle spinless density matrix components in equation (4) and correlation functions for electrons of the same and opposite spins,

$$P_2(1, 2; 1, 2)^{\alpha\alpha\alpha\alpha} = P_1(1; 1)^{\alpha\alpha}P_1(2; 2)^{\alpha\alpha}[1 + f(1, 2)^{\alpha\alpha}] \quad (9)$$

$$P_2[(1, 2; 1, 2)]^{\alpha\beta\alpha\beta} = P_1(1; 1)^{\alpha\alpha}P_1(2; 2)^{\beta\beta}[1 + f(1, 2)^{\alpha\beta}] \quad (10)$$

where $f(1, 2)^{\alpha\alpha}$ and $f(1, 2)^{\alpha\beta}$ denote correlation functions for electrons of the same and of opposite spins, respectively. The Pauli Exclusion Principle requires that as the coordinates of particle 2 approach those of particle 1,

$$f(1, 2)^{\alpha\alpha} \rightarrow -1 \quad \text{and} \quad f(1, 2)^{\alpha\beta} \rightarrow -1 \quad (10a)$$

corresponding to 100% negative correlation which prevents particles of like spin being found at the same point in space.³¹

Since essentially all of the molecules of interest are in singlet ground states

$$P_1(1; 1)^{\alpha\alpha} = P_1(2; 2)^{\beta\beta} = (\frac{1}{2})P_1(1; 1) \quad (11)$$

so that both the two-electron spin density matrix and the nuclear spin–spin coupling are proportional to the differences in the correlation functions for electrons of the same and opposite spins,

$$Q_c(1, 2; 1, 2) = (\frac{3}{4})P_1(1; 1)P_1(2; 2)[f(1, 2)^{\alpha\alpha} - f(1, 2)^{\alpha\beta}] \quad (12)$$

At this level of theory the various bond orders provide estimates for the differences in the correlation functions in equation (12).

3.2 Early Theory

The recognition of the spin coupling phenomenon quickly led to theoretical discussion using the Heitler–London formulation.³⁹ It also provided an explanation for linewidths in solids which were larger than could be accounted for on the basis of the direct dipole–dipole interactions.^{40,41}

3.2.1 Molecular Orbital Methods

In the period 1955–1957 McConnell considered the J coupling problem from several points of view including a molecular orbital description,⁴² a Dirac vector model,⁴³ and a spin-exchange model.^{44,45} The MO model was used by Saika⁴⁶ to investigate the J coupling in ammonia. On the basis of MO results in which interproton spin–spin coupling constants were proportional to the square of the MO bond order, McConnell speculated that interproton coupling constants were probably all positive in sign.⁴⁷ In the light of subsequent sign measurements, a formulation was used to rationalize the negative $J(\text{H}, \text{H}')$ in aromatic systems.⁴⁸ During this period Pople related the orbital contributions to nuclear spin–spin coupling to the anisotropy of the magnetic screening.⁴⁹

In single determinant Hartree–Fock theory the correlation function for electrons of opposite spins in equation (12) vanishes identically, and assuming that the molecule has a singlet ground state,

$$Q_c(1, 2; 1, 2) = (\frac{3}{4})P_1(1; 1)P_1(2; 2)f(1, 2)^{\alpha\alpha} \quad (13)$$

which is negative because the correlation function $f(1, 2)^{\alpha\alpha}$ is inherently negative (it is zero if the electrons are uncorrelated).

Expanding a Slater determinant via Laplace’s development leads to an expression for the two-particle density matrix in terms of the Fock–Dirac density matrix $\rho_1(1;1')$,³²

$$\rho_2(1, 2; 1', 2') = \rho_1(1; 1')\rho_1(2, 2') - \rho_1(1; 2')\rho_1(2; 1') \quad (14)$$

Rewriting the one-particle density matrices in terms of the spinless components provides an expression for the two-electron spinless components,

$$P_2(1, 2; 1', 2') = P_1(1; 1')P_1(2, 2') - P_1(1; 2')P_1(2; 1') \quad (15)$$

$$P_2(1, 2; 1', 2') = P_1(1; 1')P_1(2; 2') \quad (16)$$

From equation (8) the spin coupling function can, therefore, be written in terms of the off-diagonal elements of the one-particle density matrix

$$Q_c(1, 2; 1, 2) = -(\frac{3}{4})P_1(1; 2)P_1(2; 1) \quad (17)$$

where the off-diagonal elements of the one-particle density matrix can be written in terms of the molecular orbitals

$$\begin{aligned} P_1(1; 2) &= \sum_i n_i \chi_i(1)\chi_i^*(2) = \sum_{\mu\nu} \sum_i n_i c_{i\mu} c_{i\nu}^* \phi_\mu(1)\phi_\nu^*(2) \\ &= \sum_{\mu\nu} \eta_{\mu\nu} \phi_\mu(1)\phi_\nu^*(2) \end{aligned} \quad (18)$$

In the i th molecular orbital $c_{i\mu}$ and $c_{i\nu}$ are the coefficients of orbitals μ and ν , respectively, n_i is the occupation number, and $\eta_{\mu\nu}$ is the bond order between orbitals μ and ν as defined by Coulson and Longuet-Higgins,⁵⁰

$$\eta_{\mu\nu} = \sum_i n_i c_{i\mu} c_{i\nu}^* \quad (19)$$

Substituting equation (18) into equation (17), one sees that at this level of MO theory the coupling constant is proportional to the square of the bond order. This is awkward, not only because of the single sign problem noted above, but also because this type of bond order vanishes for even alternant systems if orbitals μ and ν are in the same subset.⁵⁰ Of course, this result is not consistent with a large number of examples of sizable spin-spin coupling constants of either sign for atoms separated by an even number of bonds. These problems can be circumvented in alternant MO methods³⁸ in which both types of correlation are included in an easily visualized way. For the specific case of a molecule with two electrons, e.g. H_2 $P_2(1, 2; 1, 2) = 0$, so the coupling constant is proportional to

$$\begin{aligned} Q_c(1, 2; 1, 2) &= -3P_2(1, 2; 1, 2) \\ &= -3P_1(1; 1)P_1(2, 2)[1 + f(1, 2)] \end{aligned} \quad (20)$$

Since $f(1, 2) = 0$ at the Hartree-Fock level, equation (13) becomes simply

$$Q_c(1, 2; 1, 2) = -(\frac{3}{4})P_1(1; 1)P_1(2, 2) \quad (21)$$

For a two-electron system in terms of the occupied MO χ the diagonal element is simply

$$P_1(1; 1) = 2\chi(1)\chi^*(1') \quad (22)$$

Taking χ to be a linear combination of atomic orbitals ϕ_μ and ϕ_ν , associated with nuclei N and N', then

$$\begin{aligned} P_1(1; 1') &= \phi_\mu(1)\phi_\mu^*(1') + \phi_\nu(1)\phi_\nu^*(1') \\ &\quad + \phi_\mu(1)\phi_\nu^*(1') + \phi_\nu(1)\phi_\mu^*(1') \end{aligned} \quad (23)$$

Neglecting terms like $\phi_\mu(1_N)\phi_\nu^*(1_N)$ in comparison with terms like $\phi_\mu^2(1_N)$, it then follows from equations (7) and (22) that the directly bonded coupling constant expression is

$$J_{NN'} = (h\Delta E)^{-1}(16\pi\beta\hbar/3)^2\gamma_N\gamma_{N'}\phi_\mu^2(1_N)\phi_\nu^2(1_{N'}) \quad (24)$$

Substitution of the form for a hybrid orbital for one or both of ϕ_μ and ϕ_ν where ϕ_μ is of the form

$$\phi_\mu = as_\mu + (1 - a^2)^{1/2}p_{\sigma\mu} \quad (25)$$

where s_μ and $p_{\sigma\mu}$ denote 2s and 2p atomic orbitals on atom μ and a^2 is the s character. The resulting equation relates directly bonded, e.g. $^{13}C-H$ and $^{13}C-^{13}C$ coupling constants to the s characters at the carbon atoms.⁵¹⁻⁵³ Equation (25) neglects a factor of $(1 + S)^{-2}$, where S is the overlap integral between bonded orbitals ϕ_μ and ϕ_ν . By means of an alternant molecular orbital method it was noted³⁸ that *the neglect of overlap compensates to some extent for the neglect of electron correlation!*

3.2.2 Valence Bond (VB) Methods

These methods were used extensively in the early work in nuclear spin-spin coupling.⁵⁴⁻⁷¹ Certainly, the most widely known application is that for the angular dependence of the vicinal H-H coupling constants in ethane.⁵⁸ Since the VB method had an important impact on the development of spin-spin coupling theory, its application in conformational analyses, and some intuition regarding the electronic factors leading to the phenomenon, a brief review seems appropriate here. Even though VB concepts are closely tied to chemists' ideas of formulas, resonance, etc., the quantum mechanical methods are unfamiliar to many chemists. The derivation of VB coupling constant expressions demonstrates the simplicity provided by the density matrix formalism. In the simple VB method the singlet ground state wavefunction $^1\Psi_0$ is written as a linear combination of independent, nonpolar VB structures $^1\Phi_j$,⁷²

$$^1\Psi_0 = \sum_j c_j ^1\Phi_j \quad (26)$$

The $^1\Phi_j$ can be constructed formally by placing $2n$ points on the circumference of a circle and then drawing all possible structures which have all of the points connected, but in which no two lines cross. For example, depicted in Figure 2(a) are the two independent, singlet VB structures $^1\Phi_1$ and $^1\Phi_2$. These are useful for investigating geminal, vicinal, and long range H-H coupling as described simply by two C-H bonds as depicted in Figure 2(b). The perfect pairing structure is that in which there are covalent bonds between the carbon hybrid orbitals and the hydrogenic 1s atomic orbitals $c-h$ and $c'-h'$. The nonperfect pairing structure is of

Figure 2 (a) Valence bond singlet structures for a system of four electrons associated with two C–H bonds. Structure ${}^1\Phi_1$ is the perfect pairing structure and ${}^1\Phi_2$ is the non-perfect pairing structure. (b) Schematic representations of four electron fragments for (i) geminal coupling in a CH_2 moiety, (ii) vicinal coupling in an ethanic moiety, and (iii) long-range coupling in a propanic moiety

higher energy since it involves breaking the two C–H bonds and forming bonds between h and h' and c and c' . In the VB formulation nonvanishing H–H coupling arises from the contributions of ${}^1\Phi_2$ to the ground state wavefunction. Matrix elements entering the secular determinant associated with equation (26) are constructed by superimposing the various structures.⁷³ The matrix elements are written as a sum of terms involving Coulomb and exchange integrals multiplied by a function which is determined by superimposing the VB structures. For a $2n$ electron system the coefficients of the Coulomb integrals are $(\frac{1}{2})^{n-i_{jl}}$ where i_{jl} is the number of islands (closed polygons) which occur in the superposition diagram of structures j and l . The coefficients of the exchange integrals are $(\frac{1}{2})^{n-i_{jl}} f_{jl}^{\mu\nu}$ where $f_{jl}^{\mu\nu}$ assumes the values 1, -2 , and $-\frac{1}{2}$ depending on whether orbital μ and ν are in the same island separated by an odd number of bonds, or an even number of bonds, or are in different islands, respectively. The two-electron density matrix follows directly from the expression for the ground state energy,

$$P_2(1, 2; 1', 2') = \sum_{j,l} c_j c_l \left(\frac{1}{2} \right)^{n-i_{jl}} \sum_{\mu,\nu} [\phi_\mu(1)\phi_\nu(2)\phi_\mu(1')\phi_\nu(2') + f_{jl}^{\mu\nu} \phi_\mu(1)\phi_\nu(2)\phi_\nu(1')\phi_\mu(2')] \quad (27)$$

where c_j is the coefficient of the j th VB structure, and ϕ_μ and ϕ_ν are atomic orbitals. The spin–spin coupling function is obtained from equations (7) and (8) and the spinless components of $P_2(1, 2; 1', 2')$,^{32,74}

$$Q_c(1, 2; 1', 2') = -\left(\frac{1}{2}\right) \sum_{j,l} c_j c_l \left(\frac{1}{2}\right)^{n-i_{jl}} \times \sum_{\mu,\nu} [(1 + 2f_{jl}^{\mu\nu})\phi_\mu(1)\phi_\nu(2)\phi_\mu(1')\phi_\nu(2') + (2 + f_{jl}^{\mu\nu})\phi_\mu(1)\phi_\nu(2)\phi_\nu(1')\phi_\mu(2')] \quad (28)$$

Equation (28) can immediately be rewritten in terms of the Penney–Dirac bond orders $p_{\text{PD}}(\mu, \nu)$,

$$Q_c(1, 2; 1', 2') = -\left(\frac{3}{2}\right) \sum_{\mu,\nu} \{p_{\text{PD}}(\mu, \nu)\phi_\mu(1)\phi_\nu(2)\phi_\mu(1')\phi_\nu(2') + (1')\phi_\nu(2') + \left(\frac{1}{2}\right)[1 + p_{\text{PD}}(\mu, \nu)]\phi_\mu(1) \times \phi_\nu(2)\phi_\nu(1')\phi_\mu(2')\} \quad (29)$$

where⁷⁵

$$p_{\text{PD}}(\mu, \nu) = \left(\frac{1}{3}\right) \sum_{j,l} c_j c_l \left(\frac{1}{2}\right)^{n-i_{jl}} (1 + 2f_{jl}^{\mu\nu}) \quad (30)$$

Neglecting two-center overlap terms of the type $\phi_\mu(1_N)\phi_\nu(1_N)$ in equation (27) shows that the nuclear spin–spin (FC contribution) coupling is linearly related to the Penney–Dirac bond order $p_{\text{PD}}(\mu, \nu)$.⁶⁶ Consider several situations for H–H coupling represented by the two C–H bonds in Figure 2(b). Depending on whether the hybrid orbitals c and c' constitute (i) a geminal pair, (ii) a vicinal pair, or (iii) are hybrid carbon orbitals separated by two or more bonds, these structures provide a useful, but simplistic, representation of the corresponding coupling situations. Note that the PD bond order $p_{\text{PD}}(h, h')$ has no contribution from the perfect pairing structure [see Figure 2(a)] because $f_{11}^{hh'} = -\frac{1}{2}$ in equation (30). However, in the superposition diagram for ${}^1\Phi_1$ and ${}^1\Phi_2$, $f_{12}^{hh'} = 1$ leading to a nonvanishing contribution to $p_{\text{PD}}(h, h')$. Using perturbation theory $c_1 \approx 1$,^{54,74} hence

$$c_2 \approx \left(\frac{1}{2}\right) \left[\frac{K(h, h') + K(c, c') - K(c, h') - K(c', h)}{K(c, h) + K(c', h') - K(c, c') - K(h, h')} \right] \quad (31)$$

where $K(\mu, \nu)$ is a two-center exchange integral associated with orbitals ϕ_μ and ϕ_ν ,

$$K(\mu, \nu) = \iint \phi_\mu(1)\phi_\nu(2)[(R_{ab})^{-1} + (r_{12})^{-1} - (r_{1b})^{-1} - (r_{2a})^{-1}]\phi_\nu(1)\phi_\mu(2) \, d\tau_1 \, d\tau_2 \quad (32)$$

From equation (30) the PD bond order associated with the hydrogens is simply,

$$p_{\text{PD}}(h, h') = c_1 c_2 + c_2^2 \approx c_1 c_2 \approx c_2 \quad (33)$$

Since $c_2 \ll c_1 \approx 1$ for saturated systems, in this simple model the coupling constant is proportional to the contribution of the nonperfect pairing structure to the ground state wavefunctions,

and it related to the exchange integrals in equation (31). As the numerator and any one of the exchange integrals can be of either sign, the Penney–Dirac bond orders and coupling constants can be either positive or negative. This is a more plausible result than the quadratic dependence on the MO bond order, which occurs because of the very different ways in which electron correlation appears in these two methods! Because of the extreme importance of electron correlation effects for nuclear spin–spin coupling, the early successes of valence bond methods compared with simple MO methods should come as no surprise.

At an early stage in the development of NMR this simple VB theory qualitatively explained a number of aspects of interproton coupling: geminal H–H coupling is quite sensitive to exchange integral cancellation in the numerator of equation (31). In comparison with vicinal H–H coupling constants, geminal H–H coupling constants are very sensitive to H–C–H angles, substituent and solvent effects. The original VB calculations for vicinal H–H coupling constants in an ethane fragment were based on a six-electron fragment for the ethane molecule. However, all of the important aspects are implicit in the four-electron model described herein. In the original paper⁵⁸ describing the dihedral angle dependence of vicinal H–H coupling constants, the only necessary nonbonded exchange integral was $K(c, c')$ occurring in the numerator of equation (29). The hybrid orbitals c and c' are depicted in Figure 2(b). The most general form of a, e.g., carbon hybrid orbital ϕ_μ can be written in terms of atomic s- and p-type atomic orbitals, the angle θ_μ that the hybrid orbital makes with the z axis, and the dihedral angle φ about the z axis,

$$\phi_\mu = a_\mu s_\mu + (1 - a_\mu^2)^{1/2} (\cos \varphi \sin \theta_\mu p_{x\mu} + \sin \varphi \sin \theta_\mu p_{y\mu} + \cos \theta_\mu p_{z\mu}) \quad (34)$$

where s_μ , $p_{x\mu}$, $p_{y\mu}$, and $p_{z\mu}$ denote the 2s and 2p atomic orbitals associated with the μ th hybrid orbital, and a_μ is defined such that a_μ^2 is the s character of the hybrid orbital. If equation (4) is specialized, for example, to tetrahedral hybrids with appropriate bond angles and a single dihedral angle φ , substitution of equation (34) into equation (32) gives the mathematical form for the vicinal exchange integral

$$K(c, c') = A \cos^2 \varphi + B \cos \varphi + C \quad (35)$$

From equations (28)–(31), (33) and (7) this will also be the approximate form for dependence of vicinal coupling constants on dihedral angles.

This simple, qualitative VB model can be extended to systems which have more than four electrons by means of ‘fragment’ bond orders of the type given in equations (31) and (33). The fragment bond order $p^0(r, s)$ associated with bonds $r-r'$ and $s-s'$ is

$$p^0(r, s) = \left(\frac{1}{2}\right) \left[\frac{K(r, s) + K(r', s') - K(r, s') - K(r', s)}{K(r, r') + K(s, s') - K(r, s) - K(r', s')} \right] \quad (36)$$

Consider the calculation of the PD bond order $p_{PD}(h, h')$ for the molecular system depicted in Figure 3. In addition to the two C–H bonds there are N bond pairs $(t-t')$. The Penney–Dirac bond orders can be determined from the

Figure 3 Schematic representations of a four-electron fragment plus n -bonds $(t-t')$

coefficients obtained by perturbation theory. Up to second order the bond order associated with the two hydrogens is written in terms of the fragment bond orders. An approximate expression is⁷⁴

$$p_{PD}(h, h') = p^0(h, h') + \left(\frac{3}{2}\right) \sum_j p^0(h, t_j) p^0(t'_j, h') \quad (37)$$

where each of the fragment bond orders is of form of equation (36). The first term on the right hand side of equation (37) has been associated with a *direct* coupling mechanism and the second with the many possible *indirect* coupling mechanisms.⁷⁴ It seems likely that the widely but undefined terms ‘through space’ and ‘through bond’ have led to substantial confusion regarding the factors responsible for spin–spin coupling. Additional relationships among the bond order expressions are as follows:

$$p^0(h, h') = p^0(c, c') = -p^0(c, h') = -p^0(h, c') \quad (38)$$

These equations provide a basis for interrelating the various coupling constants and the simple VB bond order model provides a qualitative basis for interpreting a wide variety of substituent and conformational effects.^{74,76–80}

3.3 Sum-Over-States Methods

3.3.1 Molecular Orbital Descriptions

Where the ground state wavefunction is given as an antisymmetrized product of molecular orbitals,

$$^1\Psi_0 = \mathcal{A}[\chi_1(1)\overline{\chi_1(2)}\chi_2(3)\dots\chi_i(k)\overline{\chi_i(k+1)}\dots] \quad (39)$$

and triplet state wavefunctions are produced by exciting an electron from the i th occupied MO to the j th unoccupied MO,

$$^3\Psi_{km} = \mathcal{A}[\chi_1(1)\overline{\chi_1(2)}\chi_2(3)\dots\chi_i(k)\dots\chi_j(k+1)\dots] \quad (40)$$

In equation (40) electrons k and $k+1$ have parallel spins and $m = +1, 0$, and -1 . The transition density matrix associated with the ground state and $m = 0$ components of the triplet levels is given from equations (3), (32) and (33),

$$\begin{aligned} \rho_1(0\kappa_0 | 1; 1') &= 2 \int \chi_i(1)\chi_i(2)(1/\sqrt{2})[\alpha(1)\beta(2) - \beta(1)\alpha(2)] \\ &\quad \times (1/\sqrt{2})[\chi_i^*(1')\chi_j^*(2) + \chi_j^*(1')\chi_i^*(2)] \\ &\quad \times (1/\sqrt{2})[\alpha^*(1')\beta^*(2) + \beta^*(1')\alpha^*(2)] dr_2 \quad (41) \end{aligned}$$

Integration over the space and spin coordinates of electron 2 yields the transition density matrix

$$\rho_1(0\kappa_0 | 1; 1') = -(1/\sqrt{2})\chi_i(1)\chi_j^*(1')[\alpha(1)\alpha^*(1') - \beta(1)\beta^*(1')] \quad (42)$$

which defines the spinless components. These provide an expression for the transition spin density matrix

$$Q_1(0\kappa_0 | 1; 1') = -\sqrt{2}\chi_i(1)\chi_j^*(1') \quad (43)$$

Substituting equation (43) into equation (6) leads to an expression for the FC contribution

$$J_{NN'} = -h^{-1}(16\pi\beta\hbar/3)^2\gamma_N\gamma_{N'} \sum_{i,j} (\epsilon_j - \epsilon_i)^{-1} \times \chi_i(1_N)\chi_j^*(1_N)\chi_i(1_{N'})\chi_j^*(1_{N'}) \quad (44)$$

where the sum is over the occupied and unoccupied MOs i and j , respectively. Expanding the MOs as a linear combination of atomic orbitals and neglecting contributions other than the s-type orbitals centered on atoms N and N', this becomes

$$J_{NN'} = -h^{-1}(16\pi\beta\hbar/3)^2\gamma_N\gamma_{N'} \sum_{i,j} (\epsilon_j - \epsilon_i)^{-1} c_{i\mu}c_{j\nu}c_{i\nu}c_{j\mu} \times \phi_\mu^2(1_N)\phi_\nu^2(1_{N'}) \quad (45)$$

where orbitals ϕ_μ and ϕ_ν are associated with nucleus N and N', respectively. Equation (44) is more conveniently written in the form

$$J_{NN'} = -(4h)^{-1}(16\pi\beta\hbar/3)^2\gamma_N\gamma_{N'}\phi_\mu^2(1_N)\phi_\nu^2(1_{N'})\pi_{\mu\nu} \quad (46)$$

where the mutual atom–atom polarizability $\pi_{\mu\nu}$ is given by⁵⁰

$$\pi_{\mu\nu} = -4 \sum_{i,j} (\epsilon_j - \epsilon_i)^{-1} c_{i\mu}c_{i\nu}c_{j\mu}c_{j\nu} \quad (47)$$

This equation has been used extensively to calculate contact contributions to spin–spin coupling constants and to rationalize substituent trends. Pople and Santry used this formulation and an independent electron MO model⁸¹ to investigate spin–spin coupling constants in hydrocarbons. Perturbation theory was used to relate the mutual atom–atom polarizabilities in equation (47) to the off-diagonal elements of the Hamiltonian.⁸¹ These techniques were extended by several groups to investigate J couplings in a variety of situations.^{82–86} Murrell and Gil also used a perturbation approach but for hydrocarbons included the additional integrals which involve the hydrogens.⁸² This formulation was also used with a variety of different types of approximate methods, including extended Hückel,^{87–91} complete neglect of differential overlap (CNDO),⁹² INDO,⁹³ and wavefunctions⁹⁴ based on a modified Mulliken approximation.⁹⁵

The Pople–Santry sum-over-states formulation (usually with a modified denominator to account for triplet energies) or the finite perturbation theory (FPT) method described in the next section was used for ab initio calculations.^{33,96–102} The results were unsatisfactory. For example, nonempirical

results with SCF wavefunctions (with the exception of values for HFC=O) led to coupling constants which were 2–4 times too large in magnitude.¹⁰²

In a number of cases molecular symmetry has been exploited in the sum-over-states formulation to provide elegant descriptions of substituent effects. These include geminal H–H,^{103,104} long range H–H,^{105,106} and coupling in ethylenic and aromatic systems.¹⁰⁷ The Pople–Santry method⁸¹ was also used to investigate the importance of noncontact mechanisms, e.g. F–F coupling constants,^{108,109} and ¹³C–¹³C coupling constants.¹¹⁰

Hiroike¹¹¹ noted that the simple VB and MO methods based on equation (46) without configuration interaction (CI) represent different contributions to the spin–spin coupling constant. In fact, for the case of long range H–H coupling over four bonds it was found that the sum of the two results gives a much better representation than either of the MO or VB results.¹¹²

3.3.2 Valence Bond Sum-Over-Triplet Description

In the VB sum-over-triplet level scheme from these laboratories,^{113,114} the ground state wavefunction is written as before, and the wavefunctions for the manifold of triplets are written,

$${}^3\Psi_K = \sum_l c_{kl} {}^3\Phi_l \quad (48)$$

where for a system of $2n$ electrons ${}^3\Phi_l$ denotes a set of $3[(2n)/(n+2)(n-1)!]$ linearly independent, nonpolar triplet canonical structures. These structures can most easily be obtained from the usual Rumer structures according to a scheme devised by McLachlan.¹¹⁵ For the system of two c – h bonds these structures are depicted in Figure 4. The transition spin densities follow from equations (3)–(5), (26) and (48)

$$Q_1(0\kappa_0 | 1; 1') = \sum_{j,l} c_j c_{kl} \left(\frac{1}{2}\right)^{n-i_{jl}} \sum_{\mu} \phi_{\mu}(1)\phi_{\mu}^*(1') f_{jl}^{\mu} \quad (49)$$

where in the superposition diagrams of the singlet and triplet canonical structures, i_{jl} is the number of islands and $f_{jl}^{\mu} = +1$ or -1 if orbital ϕ_{μ} is part of an island which contains a broken bond and is in the even or odd subset respectively.

The VB method with a sum-over-triplets has not been extensively applied. Even in its semiempirical form, a

Figure 4 Valence bond triplet structures for a system of four electrons associated with two C–H bonds

molecule with $2n$ electrons requires the calculation of a ground state wavefunction having $[(2n!/n!(n+1)!)]$ nonpolar singlet structures and $3[(2n!)/(n+2)!(n-1)!]$ nonpolar triplets. A general scheme for calculating coupling constants, which was developed within the framework of the generalized product approximation, permitted calculations of a large number of coupling constants via VB and other methods.^{116–118} Since correlation effects are implicit in the ground state and triplet state VB functions, it is not surprising that it provides an excellent semiempirical description of nuclear spin–spin coupling.

3.3.3 The Generalized Product Approximation with Intergroup Configuration Interaction

This method provides a generalization of existing methods for FC spin–spin coupling in terms of the second order perturbation approaches of equations (2) and (6). The recognition of distinct groups in the molecule such as bonds and π -electron systems, permits a simplification of the discussion of many-electron systems.³² However, for cases of more than one group, an adequate description of spin coupling requires intergroup CI. Group function methods have proved to be a convenient framework for investigating, e.g. long range coupling transmitted via the π -electron systems.^{119–126} Although not originally cast in terms of density matrix notation, the various formulations for π -electron contributions to spin–spin coupling can conveniently be described by the generalized product approximation with intergroup CI.¹²⁷ For a molecular system in which distinct groups A , B , C , etc. are recognized, a single configuration wavefunction is of the form

$${}^1\Phi_0 = \mathcal{A}[{}^1\phi_{A0}(1, 2, \dots, N_A) {}^1\phi_{B0}(N_A + 1, N_A + 2, \dots, N_A + N_B) \dots] \quad (50)$$

where $\mathcal{A}$ is an operator which gives a normalized, antisymmetric wavefunction, and ${}^1\phi_{R0}$ is the lowest energy singlet state wavefunction for the N_R electron group R . Triplet wavefunctions ${}^3\phi_{Rm}$ ($m = +1, 0, -1$) are obtained by exciting group R to the r_m th triplet state,

$${}^3\Phi_{Rm} = \mathcal{A}[{}^1\phi_{A0} {}^1\phi_{B0} \dots {}^3\phi_{Rm} \dots] \quad (51)$$

In the single configuration approximation, transition spin densities between ${}^1\phi_0$ and ${}^3\phi_{Rm}$ only arise for group R ,

$$Q_1(0\kappa_0 | 1; 1') = Q_1(0r_m | 1; 1') \quad (52)$$

Therefore, the only nonzero contributions to the nuclear spin coupling constant from equation (6) would be those for which electrons in group R have nonvanishing densities at nuclei N and N' . Presumably, this would only be the trivial situation in which there was only one group describable by the previous formulations. As a more interesting alternative, consider configurational mixing between the ground state and those singlets ${}^1\Phi_{RS}$ produced by exciting two groups R and S to triplets and spin coupling to a singlet,

$${}^1\Psi_0 = c_0 {}^1\Phi_0 + \sum_{RS} c_{rs} {}^1\Phi_{RS} \quad (53)$$

where

$${}^1\Phi_{RS} = 3^{-1/2}(\Phi_{Rr+1} S_{s-1} - \Phi_{Rr0} S_0 + \Phi_{Rr-1} r_{+1}) \quad (54)$$

in which

$$\Phi_{Rr+1} S_{s-1} = \mathcal{A}({}^3\phi_{Rr+1} {}^3\phi_{Ss-1}) \quad (55)$$

The summation in equation (53) is over all of the triplets. If one considers all possible coupling schemes, this would eventually produce all of the singlet, nonpolar VB structures. Furthermore, in the triplet manifold configurational mixing occurs, for example, between a given triplet and those obtained by exciting all the other groups to triplets,

$${}^3\Psi_{\rho_0} = \sum_{r_0} c_{\rho_0 r_0} {}^3\Phi_{Rr_0} + \sum_{\rho_0 s_0} c_{\rho_0 s_0} {}^3\Phi_{Ss_0} \quad (56)$$

The transition spin densities which enter the FC coupling expression in equation (6) follow from equation (3), equations (53) and (56). The coefficients entering equations (53) and (56) and the energies appropriate to equation (6) can easily be obtained directly by solving the secular determinants^{116–118} or by means of perturbation theory.^{127,128}

3.4 Coupled Hartree–Fock/Finite Perturbation Descriptions

One of the most widely used methods for J coupling makes use of coupled Hartree–Fock theory. In coupled Hartree–Fock theory the nuclear perturbation of the electronic system is included in the Hamiltonian,

$$\mathcal{H} = \mathcal{H}_0 + \mathbf{A}_N \cdot \boldsymbol{\mu}_N + \mathbf{A}_{N'} \cdot \boldsymbol{\mu}_{N'} \quad (57)$$

and the Hartree–Fock equations are solved in the usual Roothaan type of formulation. Some of the previous equations, e.g. equation (44) conform to one type of uncoupling scheme for the Hartree–Fock equations.¹²⁹ There are several ways to perform calculations of J couplings that are equivalent to the coupled Hartree–Fock method. The most widely used is the FPT of Pople and co-workers.^{7,130}

Expanding the energy in a Taylor's series over the magnetic moments, then the coupling constant is proportional to the second derivative of the energy,

$$J_{NN'} \propto \left[\frac{\partial^2 E(\mu_N, \mu_{N'})}{\partial \mu_N \partial \mu_{N'}} \right]_{\mu_N = \mu_{N'} = 0} \quad (58)$$

From the Hellman–Feynman theorem the authors⁷ further showed that

$$J_{NN'} \propto \left[\frac{\partial}{\partial \mu_{N'}} \langle \Psi(\mu_{N'}) | \mathbf{A}_N | \Psi(\mu_{N'}) \rangle \right]_{\mu_{N'} = 0} \quad (59)$$

where the matrix elements can be written in terms of the spin density matrix,

$$\rho = P_1 \begin{smallmatrix} \alpha & \alpha \\ 1 & 1 \end{smallmatrix} - P_1 \begin{smallmatrix} \beta & \beta \\ 1 & 1 \end{smallmatrix} \quad (60)$$

For FC coupling it follows from equation (59) that

$$\langle \Psi(\mu_{N'}) | A_N | \Psi(\mu_N) \rangle = (8\pi\beta/3) \sum_{\mu\nu} \rho_{\mu\nu}(\mu_N) \langle \phi_\mu | \delta(r_N) | \phi_\nu \rangle \quad (61)$$

where μ and ν denote atomic orbitals and it is assumed as usual that matrix elements of $\delta(r_N)$ in equation (61) vanish except for s-type orbitals on N.

The self-consistent perturbation theory (SCPT) method was introduced by Blizzard and Santry¹³¹ as a less computationally demanding alternative to the FPT approach. An alternative method makes use of the first-order polarization propagator (FOPPA).¹³² This has been used extensively by Engelmann and Contreras¹³³ and co-workers. Applications of coupled Hartree–Fock methods including FPT, SCPT, and FOPPA formulations are far too numerous to be included here. Since noncontact mechanisms have not otherwise been emphasized here, mention should be made of the studies of $^1J(\text{C},\text{C})$ ^{134,135} coupling, those involving second row atoms,^{135,136} and nonempirical calculations.^{137–140} Within the semiempirical INDO framework, the FOPPA method (with respect to the inclusion of multicenter integrals)¹⁴¹ leads to values of FC, OP, and SD contributions which are generally in accord with the nonempirical results.

A comparison of coupled Hartree–Fock methods with sum-over-states approaches indicated that the FPT method also introduces doubly excited states in a restricted way and should give quite different results when correlation is important for the unperturbed wavefunction.^{142,143}

4 APPLICATIONS TO SPECIFIC COUPLING SITUATIONS

To examine the topic of scalar coupling from a qualitative point of view, it is often convenient to work with a simple VB bond order picture.⁷⁴ An alternative model, which leads to similar conclusions makes use of a MO model in which the MOs χ_i are written as a linear combination of hybrid type orbitals ϕ_μ (HTOs),

$$\chi_i = \sum_{\mu} c_{i\mu} \phi_{\mu} \quad (62)$$

where the ϕ_μ can be written in terms of atomic s- and p-type atomic orbitals as in equations (25) or (34). In the basis set of HTOs the expression for the FC contribution to $J_{NN'}$ is identical to the one obtained by Pople and Santry.⁸¹ The nuclear spin–spin coupling constant is proportional to the mutual atom–atom polarizability in equations (46) and (47). For geminal, vicinal coupling, or long-range H–H coupling perturbation theory can be used to relate $\pi_{hh'}$ to the off-diagonal elements of the Hamiltonian,^{81–86}

$$\pi_{hh'} = (-5\beta_{cc'}^2 - 2\beta_{hh'}^2 + 4\beta_{hc'}^2 + 2\beta_{cc'}\beta_{hh'})/(16\beta^3) \quad (63)$$

where $\beta_{cc'}$, for example, is the matrix element of the Hamiltonian operator between HTOs c and c' , which are

directed toward hydrogenic orbitals h and h' as in Figure 2(b).

$$\beta_{cc'} = \langle \phi_c | \mathcal{H} | \phi_{c'} \rangle \quad (64)$$

The off-diagonal element beta; in the denominator of equation (63) corresponds to an average of those between orbitals which are bonded in the primary valence structure. As a consequence of the assumptions which are implicit in the expressions for $\pi_{hh'}$, and others associated with the relation to the spin–spin coupling, this formulation is appropriate for *qualitative interpretations*. These methods will be used here to examine briefly some of the structural factors associated with geminal and vicinal H–H coupling constants.

4.1 Geminal Coupling Constants

Many features of geminal coupling can be rationalized by means of equations (46) and (63). Various terms in the numerator have opposite signs. Depending on the magnitudes of the various matrix elements, geminal H–H coupling constants could represent a delicate balance between terms of comparable magnitude but of opposite sign. The difficulty with early calculations of geminal coupling constants and the unusual sensitivity of geminal coupling constants to substituents and solvents would tend to support this view. Because of the renewed interest in the H–C–H angle dependence of $^2J(\text{H},\text{H}')$,^{144,145} it may be useful to reexamine the proposed dependence of 2J on the carbon hybridization. In equation (63) the most important term appears to be the geminal interaction integral $\beta_{cc'}$ since it is multiplied by 5. When expressed in terms of the diagonal matrix elements α_s and α_p in the s,p basis set, this term is proportional to the carbon s character a^2 ,

$$\beta_{cc'} = a^2(\alpha_s - \alpha_p) \quad (65)$$

If all of the integrals except this one could be neglected in the numerator of equation (63), the geminal coupling constants would be proportional to the products of the s character a^4 at the carbon atom. Therefore, the dependence of the coupling constants on the valence angle θ follows from the proportionality to a^4 and the relationship of a^2 to θ ,

$$a^2 = -\cos\theta/(1 - \cos\theta) \quad (66)$$

The slope of this function is $0.25 + 0.02$ between $\theta = 102$ and 129° .¹⁴⁴ Small variations of $\Delta\theta$ around both the tetrahedral and the trigonal interorbital angles should lead to approximately linear dependences of the geminal coupling constants on $\Delta\theta$. The recent ab initio MO data for $^2J(\text{H},\text{H}')$ of Geertsens et al.¹⁴⁵ indicate that this is the case. Their nonempirical results can also be fit to the expression

$$^2J(\text{H},\text{H}') = 160.6a_C^4 - 24.6 \text{ Hz} \quad (67)$$

which has a standard deviation of only 0.2 Hz.

4.2 Vicinal Coupling Constants

Because of their sensitivity to variations of dihedral angles, vicinal H–H nuclear spin–spin coupling constants ${}^3J(\text{H},\text{H}')$ have been used extensively for conformational studies. Much effort has been expended in specifying parameters for the torsion angle dependence for this type of coupling. Factors such as H–C–C internal angle dependence, C–C bond length dependence, and substituent electronegativity are also involved. Subsequent efforts have identified other factors, including substituent orientation and electronic contributions to ${}^3J(\text{H},\text{H}')$ from other groups in the molecule. Based on either the VB bond order formulation, MO sum-over-states perturbation, or group function formulations, there can be important contributions to the nuclear spin–spin coupling constants arising from groups that are outside the coupling path. An interesting example of this is the nonequivalence of the *exo–exo* and *endo–endo* vicinal coupling constants in bicyclo[2.2.1]heptanes.¹⁴⁶

4.2.1 Contributions from Remote Groups, e.g. Reasons for the Nonequivalence of Exo–Exo and Endo–Endo Coupling Constants

Attempts to refine the dihedral angle dependences of vicinal H–H coupling constants have demonstrated the importance of electronic factors outside the coupling path. An example of such an effect was the reason for the nonequivalence of the *exo–exo* and *endo–endo* coupling constants in the norbornane series.¹⁴⁶ In norbornanes it was observed that *exo–exo* coupling constants are several hertz larger than the *endo–endo* values even though both correspond to situations in which the dihedral angles are near 0°. These experimental trends were satisfactorily reproduced at the semiempirical (INDO-FPT) level. To investigate this nonequivalence a procedure was used in which certain nonbonded interactions between the ethanic bridge and other parts of the molecule were eliminated from the SCF procedure. Our first guess, that the most important interactions were between the two ethanic bridges of norbornane, turned out to be incorrect. Only on elimination of the interactions between the ethanic bridge and the methylene bridge did the two types of coupling become equivalent. These ideas have been incorporated into procedures for conformational analyses of 5-membered rings.^{147,148} It is not our intent to minimize the practical applicability of the many empirical equations, but this provides one example of the reason that there can be no universal equations to describe the conformation dependences of nuclear spin–spin coupling constants.

4.2.2 Dependence on H–C–C Internal Angles as well as Dihedral Angles

Substantial deviations of internal H–C–C angles from the tetrahedral values are common in strained, multicyclic compounds. Because of their relative rigidity, such compounds are most appropriate for unambiguously relating spin–spin coupling constants to molecular structures. There are some interesting examples which clearly show the importance of internal angle change, e.g. the monotonic decrease of H–C=C–H coupling with decreasing ring size in cycloalkenes. The 5.3 Hz ${}^3J(\text{H},\text{H}')$ in cubanes, which have C–C–H angles near 125°,

is just about one-half of the value expected in molecules with tetrahedral angles.

An explicit expression was derived¹⁴⁹ for vicinal H–H coupling constants ${}^3J_{(\text{H},\text{H}')}(\theta_1, \theta_2, \varphi)$ in terms of the two internal H–C–C angles θ_1 and θ_2 and the torsion angle φ . The resulting expression provides excellent correlations of most features of vicinal H–H coupling in ethanic (–CH–CH–), ethylenic (–CH=CH–), allylic (C=CH–CH–), and diene (C=CH–CH=C) moieties, and provide criteria for assessing the importance of internal angle changes. Because of the obvious extension of these equations to other spin–spin coupling situations, it is of interest to include a brief description of the results.

From equations (34) and (63) (and the proportionality of the matrix elements to overlap integrals in equation (64)) the vicinal coupling constants can be written in the form

$${}^3J_{(\text{H},\text{H}')}(\theta_1, \theta_2, \varphi) = c_a a(\theta_1, \theta_2) \cos^2 \varphi + \sum_i c_{bi} b_i(\theta_1, \theta_2) \cos \varphi + C \quad (68a)$$

where

$$a(\theta_1, \theta_2) = (1 + \cos \theta_1)(1 + \cos \theta_2) \quad (68b)$$

$$b_1(\theta_1, \theta_2) = \cot(\theta_1/2) \cot(\theta_2/2) \cos \theta_1 \cos \theta_2 \quad (68c)$$

$$b_2(\theta_1, \theta_2) = \cot(\theta_1/2) \cot(\theta_2/2) (\cos \theta_1 \cos \theta_2)^{1/2} \quad (68d)$$

$$b_3(\theta_1, \theta_2) = \cot(\theta_1/2) \cot(\theta_2/2) [\cos \theta_2 (-\cos \theta_1)^{1/2} + \cos \theta_1 (-\cos \theta_2)^{1/2}] \quad (68e)$$

The C term is usually small in magnitude when ${}^3J(\text{H},\text{H}')$ is written in the form of equation (35).¹⁴⁹ Equation (68) is an analytic expression but is subject to the many approximations that are implicit in the derivation.

In equations (68a)–(68e) the dependence of ${}^3J_{(\text{H},\text{H}')}$ on C–C internuclear separations occurs in the overlap integrals, which are implicit in the coefficients c_a , c_{bi} and C . Therefore, there will be a set of coefficients for each value of $r(\text{C}–\text{C})$. In the spirit of semiempirical MO methods, where the β integrals are determined empirically, these coefficients were based on a least squares analysis of the available experimental data. In deriving this equation from equation (64) it was assumed that the $\beta_{cc'}$ term is dominant and that other integrals will have the effect of slightly modifying the empirically determined coefficients.

The term containing $\cos^2 \varphi$ (the A term) in equation (68a) is the most important term controlling the vicinal coupling constants. The θ -dependence of the coefficient of this term [equation (68b)] is relatively simple when compared with the coefficients [equations (68c)–(68e)] of the $\cos \varphi$ term. Depicted in Figure 5 for ethanic coupling is a surface and contour plot of ${}^3J_{(\text{H},\text{H}')}(\theta_1, \theta_2, \varphi)$ on the internal angles $\theta_1 = \theta_2$ and the dihedral angle φ . The decrease in the magnitude of the vicinal coupling constants with increasing H–C–C angle is substantial, especially for the *trans* coupling. Clearly, the usual tendency to neglect the effects of internal angle changes

Figure 5 Surface and contour plots depicting the dependence of vicinal H–H coupling constants in an ethanic system as a function of the dihedral angle ϕ and the internal H–C–C angles $\theta_1=\theta_2$

cannot be justified in strained molecules or those with unusual bonding patterns.

1 INTRODUCTION

Intercalation compounds are formed by the reversible insertion of guest species into solid matrices which retain their structure except for certain lattice expansions. They may be considered as a subclass of inclusion compounds, a term that has been used for a larger group of materials consisting of host and guest species. For intercalation reactions an increasing number of host lattices with different structural dimensionality is nowadays available ranging from insulators such as layered silicates to semiconductors and metallic conductors, e.g. graphite, transition metal dichalcogenides, or molybdenum cluster compounds. The guest species include small atomic ions as well as solvated systems and larger molecular units. As far as the aspects of the materials, the preparation of the compounds, and other chemical and physical properties are concerned, we have to refer to review articles and monographs which cover a broader horizon and some specific aspects of the subject.¹ Applications of intercalation compounds comprise battery systems, electrochromic displays, catalysis, and sensors, as well as the employment as model systems for low-dimensional solids.

Solid state NMR studies have contributed substantially to the understanding of the structure and dynamics of intercalation compounds. The location of guest molecules, their orientation and bonding characteristics, guest–host interactions, the donation of electrons to the host, and motions of the intercalated species are some of the problems that have been addressed using NMR. Chemical shift, nuclear quadrupole, and dipole–dipole interactions, and relaxation rates have been utilized to obtain data on the structure and dynamics of intercalation compounds. High-resolution techniques such as MAS or multiple pulse methods were only applied in exceptional cases, since the information on the anisotropy is of major importance. Broadline spectra of compounds with reduced dimensionality are often distinguished by much better resolved structures than those of three-dimensional solids.

Among the materials that have been investigated using NMR techniques, characteristic differences exist between intercalation compounds with insulator host lattices and those which exhibit electronic conductivity. The most important

groups of the first class of compounds are zeolites, pyrochlores, sheet silicates, and β -alumina, which are generally discussed in another context. We will concentrate on host lattices with electronic conductivity, which have attracted increased interest in recent years because of the large diversity of compounds. The intercalation in these materials can be described by the concept of reversible topotactic redox reactions, and is connected with the transfer of electrons entering or leaving the conduction band of the host matrix.

The most important classes of such systems are two-dimensional layered intercalation compounds with cationic or solvated ionic guest species or with intercalated molecules, and three-dimensional framework structures containing channels or cavities for the uptake of small guest species. Among the materials known for a long time, the graphite intercalation compounds belong to the layered systems, and hydrogen bronzes may be formed in both three- and two-dimensional structures.

Within this article it is of course not possible to present a survey of all the NMR results which contributed to the understanding of the structure of intercalation compounds or of the motions of guest species. For this the reader is referred to the literature, and especially to a recent, comprehensive review.² Here it is attempted to illustrate the potential of NMR for the examination of intercalation compounds by means of typical examples. To this aim, in the next section some example techniques and experiments using multinuclear magnetic resonance will be discussed as an introduction to the methods. Section 3 contains more recent NMR studies of some special layered chalcogenide systems, while Section 4 is devoted to molybdenum cluster sulfides, the class of intercalation compounds with a framework structure which was recently investigated in most detail.

2 TYPICAL NMR EXPERIMENTS WITH INTERCALATION COMPOUNDS

2.1 Powder Patterns or Oriented Samples

Optimum information is of course obtained if—in exceptional cases—single crystals are available. Figure 1 shows, as an example, the ^1H NMR spectrum of the metal–ammonia intercalation compound $\text{Na}_x(\text{NH}_3)_y[\text{MoS}_2]$ for the two limiting orientations, where the angle Θ between the crystalline c axis and the external field is either 0 or 90°. The angular dependence follows a $(3 \cos^2 \Theta - 1)$ law. The following information was obtained: (i) the large triplet splitting belongs to the dipolar proton–proton interaction in a rotating three-spin system; (ii) each component is split once more by the interaction with the nitrogen nucleus; (iii) the C_3 axes of NH_3 are oriented parallel to the layer planes; and (iv) there is an additional reorientational motion of the NH_3 molecules about an axis parallel to the hexagonal c axis and perpendicular to the direction of the C_3 axis; this motion becomes frozen at temperatures below about 100 K.

Most investigations refer to powder samples consisting of small crystallites of the material. In conducting layered compounds, as a consequence of the Pauli paramagnetic anisotropy, there is a tendency of the crystallites in sufficiently high magnetic fields to become aligned. Figure 2 shows as an example the ^1H NMR spectra of the hydrated system Na_x

Figure 1 Proton NMR derivative spectra of an $\text{Na}_x(\text{NH}_3)_y[\text{MoS}_2]$ single crystal at 300 K for two orientations of the hexagonal c axis in a magnetic field of 0.19 T. Measurements were made for both intercalated $^{14}\text{NH}_3$ and $^{15}\text{NH}_3$. (Reproduced by permission of Oldenbourg Verlag from E. Wein, W. Müller-Warmuth, and R. Schöllhorn, *Z. Phys. Chem. (NF)*, 1987, **151**, 113)

$(\text{H}_2\text{O})_y[\text{NbS}_2]$ for a loosely packed sample [Figure 2(a)], for a more compact sample [Figure 2(b)], and a sample where the small crystallites were embedded in Teflon powder and pressed into the ampule [Figure 2(c)]. The limiting spectra [Figure 2(a) and (c)] correspond to a normal powder pattern (Pake doublet with anisotropic chemical shift) and a situation where all the crystallites are completely oriented with their hexagonal c axes parallel to the external field.

The magnetic field induced orientation phenomena observed in many solid state NMR experiments of layered compounds can be explained in terms of the magnetic properties and depend on the density of states at the Fermi level of the transition metal chalcogenides or graphites.³ Orientation or partial orientation may lead to misinterpretations of the spectra if not recognized, or we may profit from it by conducting experiments which are otherwise not possible. An example is given in Figure 3. The powder pattern of the ^{93}Nb NMR in the host lattice NbS_2 is broad and can be simulated by chemical shift and quadrupole interactions ($\delta_{\text{iso}} = 1350$ ppm referred to niobium pentachloride, $\Delta\sigma = 4200$ ppm, $\chi = e^2qQ/h = 61$ MHz, $\eta_{\text{CS}} = \eta_{\text{Q}} = 0$). In a loosely packed sample, by contrast, only one narrow, central transition (CT) can be observed in the covered range. However, it is possible to detect

Figure 2 Proton NMR spectra of polycrystalline $\text{Na}_x(\text{H}_2\text{O})_y[\text{NbS}_2]$ observed in a magnetic field of 7 T, whereby the density of the package of the sample was increased from top to bottom

all the eight satellite transitions (ST) of the spin- $\frac{9}{2}$ nucleus as well if the detection range is greatly expanded. The positions of these lines can be reproduced by spectrum simulation with first- and second-order quadrupole interactions, resulting in a very precise determination of the coupling constant.

Intercalation of copper produces a satellite spectrum of 18 lines [Figure 3(c)], which was explained by the superposition of two complete spectra with quadrupole coupling constants of 39.12 and 36.05 MHz instead of 60.02 MHz for the empty host. They belong to two distinct niobium environments in the host lattice with an occurrence ratio 1:1 caused by a well ordered arrangement of copper atoms in tetrahedral sites of the van der Waals gap.

Application of the magnetic field induced orientation effect is in many cases the only way at all to detect and to analyze NMR spectra in layered intercalation compounds. It is often possible to maintain the orientation in a sample by dispersing the crystallites in a resin, and curing the resin after a strong magnetic field had been applied to induce orientation. Angle-dependent measurements are then possible, as shown in Figure 4 for the ^{63}Cu NMR of $\text{Cu}_{0.5}[\text{NbS}_2]$.

2.2 Anisotropic Dynamics of an Intercalated Heteronuclear Four-Spin System

An instructive example from the NMR point of view is difluoromethane. In the presence of larger alkali cations it is possible to intercalate molecules with low solvating power such as CH_2F_2 . Well structured ^1H and ^{19}F NMR spectra were observed (Figure 5) and could be simulated on the basis of a proper model.⁴ They were calculated from the numerical solution of the eigenvalue problem of a Hamiltonian which

Figure 3 Niobium-93 NMR spectra of layered 2H-NbS₂ in a magnetic field of 7 T and 200 K. (a) The powder pattern (sample pressed in Teflon powder) was recorded at $\nu_0 = 73.41$ MHz and superimposed of successively excited contributions (solid echo sequences with pulse lengths below $6\ \mu\text{s}$ and delay times $15\text{--}40\ \mu\text{s}$). (b) For the loosely packed sample, where the crystallites appeared to be completely oriented in the external field, a central transition (CT) at 73.56 MHz and eight satellites (ST) were observed. (c) Upon intercalation, for Cu_{0.5}[NbS₂] a spectrum of 18 lines was recorded (bottom). (Reproduced by permission of Elsevier Science Publishers from Janssen et al.³)

considers, in addition to the two Zeeman terms, 10 further interaction terms: the chemical shift of the four hydrogen and fluorine atoms [where the respective principal axis systems (PASs) are defined by the direction of the C–H and C–F bonds], the two homonuclear dipole–dipole interactions (PASs in the H–H and F–F directions), and the four heteronuclear dipole–dipole interactions (with the PASs given by the various H–F separation vectors).

In order to describe the orientation of a particular CH₂F₂ molecule with respect to the laboratory frame ($z \parallel \mathbf{B}_0$), a molecular fixed coordinate system was defined with its x' axis parallel to the F–F vector and the z' axis in the direction of the H–H vector of the tetrahedral molecule. In the further treatment, the transformation from the PASs of the various interactions to the laboratory frame was then replaced by the two successive transformations from the PASs to the molecular frame (Eulerian angles obtained from the geometry) and from the molecular to the laboratory frame (two Eulerian angles α' and β' appear in the result). Powder patterns result from spatially weighted sums over all possible orientations (α', β') of the CH₂F₂ molecules.

Theoretical NMR spectra were calculated for various chemical shift anisotropies and possible thermally activated reorientations about various axes. The obtained ¹H and ¹⁹F NMR lineshapes were then compared with the experimental

Figure 4 (a) Copper-63 NMR spectrum of Cu_{0.5}[NbS₂] at 79.556 MHz and 210 K detected by the utilization of the field induced orientation of crystallites (solid echo sequences with pulse lengths $5\ \mu\text{s}$, delay $20\ \mu\text{s}$, repetition 0.1 s). The angles on the right-hand side indicate the angle between the c axis and $\mathbf{B}_0$. The satellites are not shown. (b) By computer simulation the following parameters were determined: $\delta_{\text{iso}} = 730$ ppm (relative to CuCl), $\Delta\sigma = -600$ ppm, $\eta_{\text{CS}} = 0$, $\chi = 14.93$ MHz, $\eta_{\text{Q}} = 0.11$; the principal axes of the CS and QF tensors coincide. Additional NMR signals arising from the ⁹³Nb nuclei and from ²³Na probe background are marked in the figure. (Reproduced by permission of Elsevier Science Publishers from Janssen et al.³)

spectra such as those shown in Figure 5. In conclusion, intercalated difluoromethane appears to be oriented with its z' axis (H–H direction) perpendicular to the layer planes, and at 300 K it reorients rapidly about this axis. Another orientation of the intercalated molecules or another type of motion would result in quite different ¹H and ¹⁹F NMR spectra.

2.3 NMR Spectra in the Presence of Various Interactions where the Principal Axes do not Coincide

Interpretation of solid state NMR spectra in the presence of dipole–dipole (DD), chemical shift (CS) and quadrupole (QF) interactions is straightforward if the principal axes of the CS and QF tensors coincide. Appropriate procedures and suitable computer programs have been developed. In two-dimensional intercalation compounds such a requirement is generally met (at least for the guest species), and the axis parallel to the layer planes is in most cases the principal axis for both the CS and QF tensors. The interpretation of the spectra shown in

Figure 5 (a) Proton and (b) fluorine-19 NMR spectra of $\text{Cs}_x(\text{CH}_2\text{F}_2)_y[\text{NbS}_2]$ measured at 30 MHz and 295 K. The magnetic field was sufficiently low to rule out orientation effects of the crystallites. The intense central resonances belong to unreacted difluoromethane molecules in the sample. (Reproduced by permission of Academic Press from Möller et al.⁴)

Figures 3 and 4 were examples of this behavior. Particularly in three-dimensional intercalation compounds, however, it may well be the case that the directions of the PASs do not coincide. An example is the broad and asymmetric ^7Li NMR spectra of the molybdenum cluster chalcogenides $\text{Li}_3\text{Mo}_6\text{X}_8$ ($\text{X} = \text{S}, \text{Se}$) shown in Figure 6.⁵

The lineshape was simulated by the following expression for the transition frequency from a state m to a state, $m - 1$:

$$\begin{aligned} \omega = & \omega_0(1 + \sigma_{\text{iso}}) + \frac{1}{6}\omega_0\Delta\sigma \\ & \times \{3\sin^2\beta\sin^2\vartheta\cos 2\varphi - 3\sin 2\beta\sin 2\vartheta\cos\varphi \\ & + (3\cos^2\beta - 1)(3\cos^2\vartheta - 1) \\ & - \eta_{\text{cs}}[\frac{1}{2}(1 + \cos\beta)^2\sin^2\vartheta\cos 2(\varphi + \gamma) \\ & + \frac{1}{2}(1 - \cos\beta)^2\sin^2\vartheta\cos 2(\varphi - \gamma) \\ & + (1 + \cos\beta)\sin\beta\sin 2\vartheta\cos(\varphi + 2\gamma) \\ & - (1 - \cos\beta)\sin\beta\sin 2\vartheta\cos(\varphi - 2\gamma) \\ & + \sin^2\beta\cos 2\gamma(3\cos^2\vartheta - 1)]\} \\ & + \frac{3e^2qQ}{4I(2I - 1)\hbar}(\frac{1}{2} - m)[3\cos^2\vartheta - 1 \\ & - \eta_Q\sin^2\vartheta\cos 2\varphi] \end{aligned} \quad (1)$$

Figure 6 Lithium-7 NMR spectra of the molybdenum cluster chalcogenides (a) $\text{Li}_3\text{Mo}_6\text{S}_8$ and (b) $\text{Li}_3\text{Mo}_6\text{Se}_8$ obtained at 116.64 MHz and 100 K, and their simulations. (Reproduced by permission of the American Chemical Society from Prigge et al.⁵)

The powder spectrum is obtained from a weighted integration over the angles ϑ and φ in equation (1) which describe the orientation of the PAS of the nuclear quadrupole interaction (QF) tensor with respect to the laboratory frame (determined by $\mathbf{B}_0$). The Eulerian angles β and γ can be determined from the experimental spectra by simulation using equation (1). β is the angle between the z axes of the QF and CS tensors. The projection of the z axis of the QF tensor on the azimuthal plane of the PAS of the CS tensor with the x axis of the latter makes the angle γ . For $\beta = \gamma = 0$, equation (1) changes into the well known formula for the transition frequencies if the PASs coincide. The other symbols have their usual meanings. Instead of the (negative) shielding constant σ_{iso} , the isotropic chemical shift $\delta = 94$ (111) ppm relative to LiCl is given for $\text{Li}_3\text{Mo}_6\text{S}_8$ (in parentheses for $\text{Li}_3\text{Mo}_6\text{Se}_8$). The chemical shift anisotropy is $\Delta\sigma = -113$ (-90) ppm and the asymmetry factor $\eta_{\text{cs}} = 0$. The quadrupole data thus obtained from the spectra are $\chi = 75$ (95) kHz and $\eta_Q = 0.25$ (0.50). The angles turned out to be $\beta = 55^\circ$ and $\gamma = 90^\circ$ for both compounds. The DD interaction was taken into account by a Gaussian broadening with (full) width at halfheight of 8.2 (4.2) kHz. The results, and in

Figure 7 Dependence of the proton ^1H NMR spin-lattice relaxation rate upon reciprocal temperature for various hydrated chalcogenides $\text{A}_x(\text{H}_2\text{O})_y[\text{MS}_2]$ with $\text{A} = \text{Li}, \text{Na}, \text{K}, \text{Rb}, \text{or Cs}$, and $\text{M} = \text{Nb or Ta}$, measured at 15 MHz (dotted lines) and 30 MHz (solid lines). (Reproduced by permission of the American Institute of Physics from Röder et al.⁶)

particular the orientation of the PASs, can be well related to the structure, as will be shown in Section 4.

2.4 Molecular Motions

Molecular motions, the most important of which are those of the guest species, may either be studied from their influence on the spectra or by examining the relaxation behavior. An illustration of the first type of experiments was the example discussed in Section 2.2. If an intercalated molecule rotates, for instance, the Eulerian angles describing the orientation of the PAS (of the respective interaction) to $\mathbf{B}_0$ become time dependent and the spectra modified by partial averaging. In such cases it is useful to investigate the variation of the spectra with temperature.

Spin-lattice relaxation rates have been frequently used to explain details of the motional behavior. Two examples will be presented. Figure 7 shows $1/T_1$ versus reciprocal temperatures for hydrated transition metal disulfides with various alkali cations. The data depend strongly on the hydration enthalpy of the cations, and contain elements of low dimensionality. The fits were made on the basis of a model which included a logarithmic dependence on frequency, i.e. two-dimensional motions.⁶ The second example refers to a material which will be discussed in a later section.

The relaxation rates of ^7Li in $\text{Li}_3\text{Mo}_6\text{S}_8$ (Figure 8) can be explained by the superposition of a BPP term due to diffusion and a term which is proportional to the temperature. The latter arises from the interaction of the lithium nuclei with conduction electrons.

Slow motions have also been investigated in intercalation compounds using standard techniques. An example is the proton exchange rate, i.e. the mean lifetimes τ_e in hydrated transition metal disulfides obtained via creation of spin alignment by the 'Jeener-Broekaert' pulse sequence. τ_e values between about 1 and 100 ms were thus determined (Figure 9). They display an Arrhenius behavior which could be extrapolated to lower temperatures (and shorter lifetimes) by lineshape analysis.

3 STRUCTURE AND MOTIONS OF HYDRATED LAYERED CHALCOGENIDES

A class of intercalation compounds that was studied in some detail by NMR and where NMR contributed substantially to the understanding of the structure and dynamics comprises the hydrated transition metal chalcogenides of the alkali and alkaline earth elements with the formula $\text{A}_x(\text{H}_2\text{O})_y[\text{MX}_2]$, where $\text{M} = \text{Ti}, \text{V}, \text{Zr}, \text{Nb}, \text{Mo}, \text{Ta}, \text{or W}$ and $\text{X} = \text{S or Se}$. These

Figure 8 Lithium-7 NMR spin-lattice relaxation rate versus reciprocal temperature for the molybdenum cluster sulfide $\text{Li}_3\text{Mo}_6\text{S}_8$. The solid curve corresponds to the theoretical model description. (Reproduced by permission of the American Chemical Society from Prigge et al.⁵)

compounds can be regarded as polyelectrolytes consisting of two-dimensional $[\text{MX}_2]^{x-}$ macroanions (host lattice) with monolayers of mobile hydrated cations in the van der Waals gap between the sheets (guest species). We shall present here only an outline of the most important NMR experiments to investigate the structure and dynamics.

3.1 Proton NMR Spectra

The ^1H NMR spectra of the guest species (Figures 2 and 10) display the influence of intra- and intermolecular dipole-dipole couplings as well as CSA interactions. Separation is possible either by studying the magnetic field dependence or by application of a multiple pulse sequence (cf. Figure 10). In a sufficiently low magnetic field, at ambient temperature a nearly perfect Pake doublet of isolated H_2O can be observed, since the intermolecular interactions are averaged out by hopping motions of the water molecules. However, there is an additional central signal which increases at elevated temperatures and which was explained by proton exchange in these two-dimensional hydrated systems. The fast motion process was further investigated by NMR T_1 measurements (cf. Figure 7), and the slower proton exchange by spin alignment techniques (cf. Figure 9).

As a final result of several ^1H NMR studies including the examination of single crystals and oriented crystallites, all the water molecules in the van der Waals gap appear to be aligned with their C_2 axes lying in the a,b planes defined by the chalcogenide layers and their H-H vectors parallel to the c axis (Figure 11). The proton-proton separations amount to 165 pm; they are not significantly different from those in water of crystallization (158 pm). Two-dimensional diffusion and/or reorientation about the c direction leaves the orientation of the water molecules unchanged. The activation energy for this motion varies from 9 kJ mol^{-1} (Cs^+) to 50 kJ mol^{-1} (Li^+) depending on the central cation which interacts immediately with the negatively polarized dipole ends of the H_2O molecules.

Figure 9 Proton mean lifetime versus reciprocal temperature for water in the chalcogenides $\text{A}_x(\text{H}_2\text{O})_y[\text{NbS}_2]$ with $\text{A} = \text{Li}, \text{Na}, \text{K}, \text{Rb},$ or Cs derived from spin alignment measurements (solid symbols) and linewidth analysis (open symbols). (Reproduced by permission of VCH from E. Wein, W. Müller-Warmuth, and R. Schöllhorn, *Ber. Bunsenges. Phys. Chem.*, 1986, **90**, 158)

The diffusional motion of the water molecules explains also the axial symmetry of the chemical shift tensor derived from the spectra of Figure 10 (top). The PASs for the CS and DD interactions coincide. At lower temperature, the symmetry of the chemical shift disappears, and the intermolecular dipole interactions become important for broadening of the spectra (Figure 10) (bottom). The chemical shift anisotropy itself was found to depend greatly on the transition metal M . Going from W via $\text{Ta}(1\text{ T})$, Mo , $\text{Ta}(2\text{H})$, Ti , Nb to V , $\Delta\sigma$ increases from -11 to $+69 \text{ ppm}$ for fully intercalated compounds ($x = 0.33$). Upon increasing the degree of reduction x between 0.08 and 0.33, $\Delta\sigma$ increases from 8 to 17 ppm for $M = \text{Ti}$; it decreases, however, from 60 to 33 ppm for $M = \text{Nb}$.

The large range of chemical shift anisotropies cannot be interpreted in terms of the electronic proton shielding within the guest phase. This should lead to a contribution of only about -10 ppm , a value which was observed as a limit in two of the compounds. In all other cases the significant positive contribution from the host lattice has to be taken into account in addition. The effect was found to depend on the particular conduction band of the dichalcogenide material and its filling with electrons. In NbS_2 the lowest-lying energy level is the d_{z^2} band, which is half occupied and becomes further filled up during the course of intercalation. The density of states at the Fermi level $D(E_F)$ has its maximum, therefore, in the absence of any intercalant, and decreases as a function of x , if guest species are intercalated and s electrons donated. $\Delta\sigma$ appears to be proportional to $D(E_F)$.

Figure 10 Proton NMR powder patterns of the hydrated layered compound $K_{0.25}(H_2O)_{0.75}[NbS_2]$ at two different temperatures (295 K, top and 150 K, bottom) measured in a magnetic field of 7 T. (a) Normal spectra. (b) Dipolar-decoupled spectra by MREV 8 multiple pulse sequences. The solid lines are computer simulations. (Reproduced by permission of VCH from M. Lobert, W. Müller-Warmuth, H. Katzke, and R. Schöllhorn, *Ber. Bunsenges. Phys. Chem.*, 1992, **96**, 1564)

This behavior was confirmed by the results for the compound $K_x(H_2O)_y[TiS_2]$. TiS_2 with the Group 4 element titanium has an empty d_{z^2} band, and, here, filling by progressive intercalation enhances both $D(E_F)$ and $\Delta\sigma$. Using the experimental data, the qualitative structure of the d_{z^2} band could be obtained for both compounds. The NMR results may be considered as a confirmation of the ‘rigid band model’, in which the only change to the electronic structure of the host is the increased d band filling. The proportionality between $\Delta\sigma$ and $D(E_F)$ was explained by the anisotropic Pauli paramagnetism; the magnetic susceptibility is also proportional to the density of states at the Fermi level.

3.2 Niobium-93 NMR Studies of the Intercalation

The process of intercalation from $x = 0$ to 0.33 could be studied in $K_x(H_2O)_y[NbS_2]$ and $K_x(H_2O)_y[NbSe_2]$ by observing the influence of the guest species on the ^{93}Nb NMR of the host lattice. The empty host lattices displayed spectra resembling those of Figures 3(a) and (b); the quadrupole coupling constants were determined with high accuracy, viz. 60.02 ± 0.02 MHz (60.05 ± 0.02 MHz) for $2H-NbS_2$ (and $2H-NbSe_2$). Intercalation of $K_x(H_2O)_y$ changes the mean local environment of niobium and reduces the coupling constant for a certain fraction of the ^{93}Nb NMR nuclei. For $x = 0.08$, 14% (11%) of the ^{93}Nb nuclei still have a coupling constant of 60 MHz, but 82% (89%) already one of 53 MHz, and 4% even one of 46 MHz. Upon increasing x further, the fractions with 60 MHz disappear in favor of the other two contributions. For $x = 0.33$ a coupling constant of 46 MHz (48 MHz) finally holds for 100% (41%) of the niobium sites in the NbS_2 ($NbSe_2$) host lattice. In $K_x(H_2O)_y[NbSe_2]$ the remaining 59% of ^{93}Nb nuclei experience the medium value of 53 MHz.

It is important to realize that there is no continuous variation of the NMR parameters with progressive intercalation, but there are three phases whose fractions change as a function of x . Structural variations are therefore responsible rather than electronic effects of the host. The three observed structures

were attributed to local staging. For $x = 0$, the relatively large quadrupole coupling belongs to niobium atoms, which all ‘see’ on one side of the two-dimensional arrangement the empty van der Waals gap. Upon increasing x , two new environments occur, one with intercalated species on both sides (local ranges of first-stage character), the other one with intercalated species on one side only (second-stage character). The smaller coupling constant of the final compound ($x = 0.33$) was attributed to a homogenous occupation of the van der Waals gap (‘first-stage compound’).

3.3 Further NMR Studies of Layered Compounds

Among the materials that were studied in some detail by NMR and which cannot be discussed within the scope of this short article are metal–ammonia compounds with certain similarities to hydrated systems. Intercalated atoms or ions in dichalcogenides, such as hydrogen, lithium and copper, were examined as well as intercalated molecules, e.g. ammonia, amines, derivatives of methane, pyridine, and even larger intercalants. Layered compounds also include graphite intercalation compounds, where, in particular, 1H , 7Li and ^{13}C NMR was applied on a large scale by various authors. Some layered oxides were investigated as well. Further details can be found in the literature.²

4 STRUCTURE AND DYNAMICS OF GUEST PHASES IN MOLYBDENUM CLUSTER CHALCOGENIDES

Binary and ternary molybdenum cluster chalcogenides (Chevrel phases) with the compositions Mo_6X_8 and $A_xMo_6X_8$ (A = main group metal; X = S or Se) have attracted considerable interest because of their unusual structure (Figure 11) and remarkable physical properties. Using NMR, compounds with intercalated lithium, sodium and copper were investigated. The behavior of lithium as the intercalant was examined in particular, with the result that four distinct phases with $x = 1, 3, 3.8$, and 4 could be identified from the different isotropic chemical shifts, as shown in Figure 12 (at room temperature, narrow singlet lines or first-order quadrupole spectra were observed). From the δ_{iso} values it was concluded that lithium appears to be ionic in $Li_1Mo_6X_8$ and $Li_4Mo_6X_8$ whereas lithium clusters with partial metallic character are formed in $Li_3Mo_6X_8$ and $Li_{3.8}Mo_6X_8$. More details were obtained from broadline spectra at low temperatures and from relaxation measurements.^{5,7}

In both $Li_1Mo_6X_8$ compounds the 7Li NMR spectra display in addition to DD and CA interactions ($\Delta\sigma = -11$ ppm at 100 K for $X = S$, and -15 ppm for $X = Se$) well resolved quadrupole structures of first order ($\chi = 107$ kHz and 79 kHz, respectively). The chemical shift tensor is axially symmetric ($\eta_{cs} = 0$), but the quadrupole asymmetry factor η_Q varies from 0.24 (0.10 for $X = Se$) at 100 K to zero at 300 K upon increasing the temperature. Spectra simulations led to the conclusion that the intercalated Li^+ ions reside in one of the six equivalent inner tetrahedral sites Li_1 of Figure 11(b) (bottom). Hopping motions between these positions are thermally activated; the correlation times are of the order of 10^{-7} – 10^{-3} s and follow an Arrhenius-type law (11 and 7 kJ mol $^{-1}$, respectively). In contrast to the other lithiated

Figure 11 Schematic representation of the structure of the compounds discussed in Sections 3 and 4. (a) Hydrated layered chalcogenides with the NbS₂ host lattice (top) and the arrangement of the H₂O molecules with the central cation (bottom). (b) Mo₆S₈ (• Mo, ○ S) structure with vacant channel positions (Δ) (top) and 2 × 6 potential lattice sites Li₁ (inner concentric ring) and Li₂ (outer ring) around the unit cell origin (bottom). The cavity is formed by sulfur atoms which belong to eight different Mo₆S₈ units

molybdenum cluster chalcogenides, at room temperature only this local motion is important; long range diffusion from cavity to cavity does not play a major role.

The extremely large δ_{iso} values of the Li₃Mo₆X₈ system were interpreted in terms of a Knight shift; the transfer of 2s electrons to the host lattice is incomplete, so that Li₃^{z+} clusters with $z < 3$ are formed. More detailed information was obtained from the ⁷Li NMR spectra at low temperatures, which are governed by DD, CS, and QF interactions. The chemical shift tensor appears to be axially symmetric, with $\Delta\sigma$ being relatively large and negative (−113 and −90 ppm for the compounds containing S or Se, respectively). This was interpreted in terms of a symmetric arrangement of three lithium atoms on the potential sites of Figure 11(b) (bottom). The z principal axis of the CS tensor may thus be identified with the symmetry axis perpendicular to the plane of the two concentric rings of possible lithium positions; the residual 2s electron density at the intercalated lithium provides stronger screening in the plane.

The principal axes of the CS and QF tensors do not coincide as shown in Figure 6 and equation (1). The PAS of the QF (EFG) tensor seems to agree with the rhombohedral reference system of the structure [Figure 11(b) (top)]. Then the angles β and γ describing the relative positions of the noncoincident PASs of the CS and QF tensors should become 54.54 and 90°, respectively, as observed experimentally. The quadrupole

coupling data are $\chi = 75$ kHz, $\eta_Q = 0.25$ ($X = \text{S}$), and $\chi = 95$ kHz, $\eta_Q = 0.50$ (Se).

The formation of lithium triclusters with short Li–Li distances and metal-like behavior is supported by spin–lattice relaxation measurements as in Figure 8. These contain in addition to a contribution from the lithium diffusion a term which is due to the interaction with conduction (2s) electrons and which fulfills the Korringa relation over a large range of temperatures. The diffusion of lithium species with activation energies of 13 and 19 kJ mol^{−1} corresponds to a high mobility of the translational motion from cavity to cavity. In contrast to Li₁Mo₆X₈, but in agreement with recent neutron diffraction studies,⁸ for Li₃Mo₆X₈ the inner ring of lithium sites is enlarged and provides, together with the outer ring, a framework of symmetrically arranged potential sites. The distances between these sites are short and comparable, and are well suited as a diffusion pathway. Application of the van Vleck formula for the DD interaction leads to an estimate of 210 pm (370 pm) for the Li–Li separation in the triclusters of Li₃Mo₆X₈ (Li₃Mo₆Se₈).

In contrast to stoichiometries with $3 < x < 3.8$ where two ⁷Li NMR signals appear, Li_{3.8}Mo₆S₈ is distinguished only by one NMR line, indicating a single-phase system. The chemical shift parameters ($\delta_{\text{iso}} = 39$ ppm, $\Delta\sigma = -45$ ppm)—though smaller than those of Li₃Mo₆S₈—and the other results, including relaxation, reveal that the lithium guest species possess metal-like properties as well. The Li–Li distances

Figure 12 Lithium-7 NMR isotropic chemical shift values (related to LiCl in aqueous solution) for $\text{Li}_x\text{Mo}_6\text{X}_8$ compounds (right). For the purpose of comparison, δ_{iso} values for various other lithium intercalation compounds and lithium metal are given (left)

are less and of the order of 330 pm, showing that the outer ring participates greatly in providing positions for the lithium atoms. The lithium mobility is again very high.

For the fully intercalated phases $\text{Li}_4\text{Mo}_6\text{X}_8$ there is no longer any Knight shift, and the chemical shift anisotropy is very small as well. Only the quadrupolar and dipolar data are of comparable orders of magnitude, but here the EFG values are somewhat distributed. The lithium mobility is much less as compared with the Li_3 and $\text{Li}_{3.8}$ compounds. The dramatic transition from Li_3 to Li_4 , as observed by NMR and manifested by the macroscopic properties of the material, can

be related to the electronic structure and to the arrangement of potential lithium sites. The inner ring is no longer enlarged, and there is a large separation between the Li1 and Li2 positions comparable to that in $\text{Li}_1\text{Mo}_6\text{X}_8$.

1 INTRODUCTION

Enormous progress in the understanding of the chemistry and structure of carbocations has come through the application of NMR techniques to long-lived carbocations in superacids.^{1,2} The focus of this article is on the development of intrinsic NMR isotope shifts (see *Carbon-13 Studies of Deuterium Labeled Compounds; Isotope Effects on Chemical Shifts and Coupling Constants*) as a probe for elucidating structural features of carbocations. After the initial reports of intrinsic isotope effects on carbocation chemical shifts by Saunders that contrasted such effects with equilibrium isotope effects,^{3,4} it has been clearly demonstrated that intrinsic NMR isotope shifts in themselves can reveal subtle features of carbocation structure that are not readily accessible by other means.

Substitution for hydrogen by deuterium in organic molecules produces small but measurable changes in ¹³C NMR chemical shifts arising from perturbations of the motional averaging of nuclear shielding in a single molecular species due to changes in nuclear masses. A typical intrinsic isotope shift for a ¹³C NMR signal, ⁿΔC(D), where *n* is the number of intervening bonds is a shielding of a few tenths of a ppm (part per million) at the carbon bearing the deuterium and smaller effects at the next carbon and more remote positions. Intrinsic NMR isotope shifts in carbocations are often larger than in typical organic molecules and very sensitive to structure. The sensitivity may arise in some cases from shallow energy surfaces for bending vibrations along the bridging coordinate, as well as chemical shifts that are highly dependent on the extent of bridging.⁵ Patterns of chemical shift response to isotopic perturbation in carbocations have been established empirically that allow structural interpretation. For example, the direction and magnitude of the ²ΔC(D) depends on the type of bonding involved in the carbocation, whether localized or π or σ delocalized.⁶

The first generalizations about the relation between structure and intrinsic isotope shifts were reached in the initial study by Servis and Shue.⁶ In cases in which the carbocation may have a σ or π bridged structure, β deuteration produced unusually large shifts to lower frequency at the cationic center, for

example -2.2 ppm in the 2-methyl-*d*₃-2-norbornyl cation (1), and -0.8 ppm in the 7-methyl-*d*₃-7-norbornenyl cation (2). For classical delocalized carbocations such as the 2-phenyl-2-propyl-1,1,1,3,3,3-*d*₆ cation (3), the isotope shifts at the cation center were nearly zero. Classical localized cations displayed isotope shifts to higher frequency at the cation center, such as the 1.4 ppm effect in the *t*-butyl-*d*₉ cation (4).

Another source of structural insight is the nonadditivity of isotope shifts that occurs in some carbocations.⁷ Typical NMR isotope shifts are additive, but nonadditivity may occur when C–H(D) bonds are conformationally mobile, because of the imposition of an equilibrium isotope effect on the population of conformers that may have different intrinsic NMR isotope shifts. Carbocations often have strong hyperconjugative interactions that lower the force constants of suitably aligned β C–H(D) bonds, so that a conformer will be favored if it has the β C–D bonds out of alignment with the *p* orbital of the cation center, i.e. in the more tightly bound position. The result is an average intrinsic isotope shift that differs from that expected in the absence of an equilibrium isotope effect on the conformer populations. The nonadditivity of intrinsic isotope shifts in conformationally mobile systems was exploited to particular advantage in the determination of the previously unknown conformation of cyclopentyl cations.⁸

2 HYPERCONJUGATION AND THE NMR ISOTOPE SHIFT

NMR isotope shifts to higher frequency occur at the cation center of simple carbenium ions (tricoordinated carbocations) upon deuterium substitution at an adjacent carbon atom (β C–D).⁶ They also occur at more remote positions in π conjugated carbocations. The isotope shifts appear to result from isotopic perturbation of hyperconjugation, with the C–D bond behaving as a poorer hyperconjugative electron donor than a C–H bond. The effectiveness of the hyperconjugative interaction is perturbed through alteration of the portion of the electronic surface over which vibrational averaging occurs. The differences in vibrational averaging leads to small differences in electron distribution and accompanying changes in shielding. Theoretical modeling of a C–D bond by shortening a C–H bond in molecular orbital calculations supports this interpretation.^{8–10}

Several lines of evidence indicate that the long range isotope effects on the ¹⁹F chemical shift in *p*-fluorophenylcarbenium ions arise from perturbation of the hyperconjugative interactions of the alkyl groups and are transmitted via the π system.⁷ For example, no isotope effect at ¹⁹F is seen for the replacement of a nonhyperconjugating α hydrogen by deuterium in (5), ruling out an ‘inductive’ origin. The isotope effect in (6) rules out a ‘steric’ origin, wherein the coplanarity of the side chain and the ring would be altered by deuteration. Transmission via the π system is suggested by attenuation of the

effect between (6) and (7). The expected dependence on the dihedral angle between the β C–H(D) bond and the electron deficient p orbital of the cation center was established in the 2-(*p*-fluorophenyl)-2-bicyclo[2.2.2]octyl cation (8).¹¹ Precisely additive isotope shifts at ^{19}F of 0.143 and 0.286 ppm were found for (8)-3-*d* and (8)-3,3-*d*₂, respectively, but no measurable effect at ^{19}F was observed for deuteration at the bridgehead C-1 position in (8)-1-*d*.

Upon deuteration of the methyl groups in the phenyldimethylcarbenium ion (3), long-range isotope shifts to higher frequency occur at the *ortho* (0.170 ppm) and *para* (0.222 ppm) carbons.^{6,12} Similar alternation of the magnitude of isotope shifts occurs at the aryl carbons of the 2-(1'-naphthyl)-2-propyl (9), and 2-(2'-naphthyl)-2-propyl (10) cations. These shifts are clear evidence for transmission via the π system, and are consistent with isotopic perturbation of hyperconjugation to reduce slightly the supply of electrons to the carbenium center.

3 NONADDITIVE NMR ISOTOPE SHIFTS AND CONFORMATION

The association of isotope shifts arising from deuteration of β C–H bonds in carbocations with a hyperconjugative interaction affords possibilities for the study of conformation. If the angular dependence of the magnitude of a particular type of isotope shift were well enough understood to be predictable, it would be possible to assess structures of conformationally fixed systems simply by measuring the isotope shifts. The current capability to predict isotope shifts is insufficient to define conformations precisely, based simply on the magnitude

of the shifts. However, the intrinsic isotope shift has provided qualitative information regarding conformation, especially via nonadditive behavior in conformationally mobile systems.

Nonadditivity was first noted in the isotope shift at ^{19}F due to deuteration of α -methyl groups in (*p*-fluorophenyl)carbenium ions.⁷ The effects of substituting entire CD₃ groups for CH₃ groups are additive, i.e. in (11) and (7), but the effects of deuterium substitution within a methyl group are not additive. The isotope shift due to a single deuterium in the methyl group is less than one-third the isotope shift due to three deuteriums. The influence of two deuteriums is also less than the two-thirds effect expected from additivity. These findings can be explained by an isotope effect favoring methyl conformations with the C–D bonds out of alignment for hyperconjugation. No conformational equilibrium isotope effect can occur in the fully deuterated methyl group, so the full intrinsic effect is represented by the CD₃ effect. Thus, the intrinsic isotope effect on the chemical shift in partially deuterated species is diminished by the equilibrium isotope effect, because the favored conformers with C–D bonds poorly aligned for hyperconjugation have a smaller intrinsic effect on the chemical shifts.

Cyclopentyl cations were shown to exist in twist (C_2) conformations rather than the possible planar (C_{2v}) or envelope (C_s) conformations through the nonadditive behavior of the intrinsic isotope shifts. The 1-(*p*-fluorophenyl)cyclopentyl cation (12), and the 1-methylcyclopentyl cation (13) display similar patterns of isotope shifts due to C-2 and C-5 deuteration.^{8,13} Each monodeuterated ion has an isotope shift at $^{13}\text{C}^+$ (13) or ^{19}F (12) that is less than one-quarter and each trideuterated ion has an isotope shift that is less than three-quarters that of the tetradeuterated isotopomer (Figure 1). This nonadditivity indicates a perturbed conformational equilibrium in a nonplanar structure for the cyclopentyl ring. All four of the C-2 and C-5 C–H bonds would be equivalent in a planar structure, and additive isotope shifts would be expected.

The key observation for identifying the nonplanar cyclopentyl structures is that the *trans*-2,5-*d*₂ isotopomers of (12) and (13) also exhibit isotope shifts that are smaller than expected on the basis of additivity, while the *cis*-2,5-*d*₂ and *geminally* labeled 2,2-*d*₂ isotopomers have isotope shifts at $^{13}\text{C}^+$ or ^{19}F that are additive, i.e. one-half the isotope shift of the 2,2,5,5-*d*₄ isotopomer. Clearly, *trans* dilabeling perturbs the conformational equilibrium while *cis* and *geminal* dilabeling do not. This combination is only possible if the cyclopentyl ring is rapidly equilibrating between two twist conformers, (14) and (15). The smaller isotope shift for the *trans*-2,5-*d*₂ case is due to an isotope effect on the conformational equilibrium that favors the conformer having

Figure 1 Proton decoupled 56.2 MHz ^{19}F NMR spectra, at about -75°C , of the 1-(*p*-fluorophenyl)cyclopentyl cation as mixtures of isotopomers due to deuteration at C-2 and C-5. (a) Spectrum of a mixture of the unlabeled ion and a randomly labeled ion sample. (b) Spectrum of another mixture enriched in the *trans*-2,5- d_2 isotopomer. (Reproduced by permission of American Chemical Society from Forsyth and Botkin¹³)

both C–D bonds in the pseudoequatorial positions and thus out of alignment with the p orbital at the cation center. The twist–twist equilibrium is not perturbed by *cis* or *geminal* dilabeling because then the twist conformers are degenerate, i.e. both have one pseudoaxial and one pseudoequatorial C–D bond. If the cyclopentyl ring had been an envelope structure, the *trans*-2,5- d_2 isotopomers would have had additive isotope shifts and the *cis*-2,5- d_2 isotopomers would have shown nonadditivity.

4 ISOTOPE SHIFTS ASSOCIATED WITH MOTION ALONG THE BRIDGING COORDINATE

Isotope shifts for the ^{13}C signals in the 2-methyl-2-norbornyl cation (**1**), are truly remarkable.^{5,6,14–16} As noted earlier, the cation center displays an unusually large isotope shift to low frequency of -2.26 ppm for the (**1**)-methyl- d_3 cation. This direction is opposite of the $^2\Delta\text{C}(\text{D})$ to high frequency attributed to isotopic perturbation of hyperconjugation in classical cations such as the *t*-butyl cation. A similar shift at C-2⁺ of -2.51 ppm is seen for (**16**). Isotope shifts at C-2⁺ are additive for labeling at C-3, with a $^2\Delta\text{C}-2(\text{exo}-3-d)$ of

Figure 2 The C-2 region of a 75.4 MHz $^{13}\text{C}\{^1\text{H}\}$ NMR spectrum of all 10 possible singly deuterated positional isotopomers and the unlabeled 2-methyl-2-norbornyl cation. (Reproduced by permission of the Chemical Society from Forsyth and Panyachotipun¹⁵)

-1.64 ppm and $^2\Delta\text{C}-2(\text{endo}-3-d)$ of -0.87 ppm. Isotope shifts to high frequency occur for deuteration at some positions, most notably in a $^3\Delta\text{C}-2(\text{exo}-6-d)$ of 1.45 ppm. Overall, changing the location of a single deuterium in the bicyclo[2.2.1]heptyl framework (Figure 2) can change the δ_{C} for the cation center of (**1**) by 3.1 ppm.

To place the large isotope shifts in context, C-3 deuteration in 2-norbornanone produces $\Delta\text{C}(\text{D})$ values that are smaller than $|0.10|$ ppm at all positions except the directly labeled C-3.¹⁴ Upon comparison of isotope shifts in the 2-methyl-2-norbornyl cation with those for the 2-methyl-2-bicyclo[2.2.2]octyl cation (**17**), and the 2-methyl-2-bicyclo[2.1.1]hexyl cation (**18**), a similar pattern of isotope shifts emerges, namely that β deuteration at either the C-3 or methyl position produces isotope shifts to lower frequency at C-2, isotope shifts to higher frequency at C-1, and a shift to lower frequency at the remaining carbon (C-3 or methyl) directly attached to C-2. The isotope shifts are of similar magnitude in (**1**) and (**17**), and somewhat smaller in (**18**).

A common origin for the isotope shifts in (**1**), (**17**), and (**18**) is likely, with similar force fields and shielding influences in all three ions. Perturbation of a σ delocalized bonding structure toward greater σ delocalization would increase electron density at C-2, decrease electron density at C-1, and decrease hyperconjugative involvement of the C-3 methylene and the

methyl group. However, this explanation must be elaborated because the C-2⁺ chemical shift of 322 ppm for both (17) and (18) is in the range (320–340 ppm) considered typical of classical, nonbridged cations, while the more shielded C-2⁺ in (1) (δ_{C} 269.5 ppm) has led to (1) being considered as a partially bridged cation.

Both the isotope shifts and chemical shifts of (1) and (12) show a small temperature dependence.⁵ The magnitude of the isotope shifts at C-1, C-2, and C-3 in both structures decline slightly with temperature, e.g. from –2.26 ppm at –98 °C to –2.02 ppm at –38 °C for C-2 in (1)-methyl-*d*₃. A dynamic equilibrium between similar structures, namely an open nonbridged structure and a partially bridged structure, could account for the data in each case, but not an equilibrium between the classical tertiary and secondary forms of the cations.

A more likely explanation is that these ions have a relatively flat energy surface for the bending motion along the direction associated with bridging.⁵ A broad energy surface would have low-lying vibrational excited states, so that not only isotope effects but temperature changes could easily perturb the vibrationally averaged geometry. Appropriately shaped anharmonic surfaces can account for the direction of the δ_{C} and $\Delta\text{C}(\text{D})$ temperature dependences in each case. The large intrinsic isotope shifts may be diagnostic for the existence of the low energy bending motion associated with development of a three-center, two-electron (nonclassical) bond, but the isotope effects are not directly reflective of the extent of bridging. Since the shallow surface and large changes in shielding may occur even when bridging is not very extensive, the isotope shift may be a particularly sensitive probe for the onset of such bonding (see results for aryl-substituted ions below).

High level ab initio molecular orbital calculations support the idea of some distortion toward bridging accompanying bridging even in simple tertiary alkyl carbocations.¹⁷ Theoretical ¹³C chemical shifts calculated by the IGLO method for changes in the C⁺–C–C angle in model cations show a very strong dependence of shielding of C⁺ on the bridging angle once an angle of about 100° is reached. A change in the C⁺–C–C angle of only 1° toward bridging results in ~6 ppm shielding of C⁺. These calculations make it clear that a small isotope effect on the vibrationally averaged extent of bridging could produce large intrinsic isotope shifts of the type seen in (1), (17), and (18).

5 VARIATION OF NMR ISOTOPE SHIFTS WITH INCREASING ELECTRON DEMAND

In aryl-substituted carbocations the dependence of the ¹³C NMR chemical shifts of the cation centers on the aryl substituents has been used extensively to evaluate the electronic and structural characteristics of various carbocation types.¹⁸ Deviations from linearity in plots of the chemical shifts at the cation center versus shifts in appropriate reference systems have been interpreted as indicating the onset of σ participation and other phenomena as electron demand increases. One of the difficulties in interpreting these ‘tool of increasing electron demand’ plots (referred to here as TIED plots) of chemical shifts is that the deviations from linearity are

Figure 3 TIED plots of isotope shifts at the cation center, $^2\Delta\text{C}(\text{D})$ versus σ_{C^+} : (a) 2-aryl-2-norbornyl cations, (b) 2-aryl-3-methyl-2-butyl cations, and (c) 1-aryl-1-tolyethyl cations. (Reproduced by permission of the American Chemical Society from Forsyth et al.¹⁹)

often rather similar in appearance in various systems despite different underlying causes for the deviant behavior. However, the use of NMR isotope shifts provides complementary data that can help differentiate between carbocations which show similar behavior in TIED plots of chemical shifts.¹⁹

Three carbocation series illustrate the use of isotope shifts: the 2-aryl-2-norbornyl-3,3-*d*₂ (19), 2-aryl-3-methyl-2-butyl-1,1,1-*d*₃ (20), and 1-aryl-1-tolyethyl-2,2,2-*d*₃ (21) cations.¹⁹ All three systems give very similar chemical shift TIED plots for the δ_{C} at C⁺. However, the isotope shift TIED plots (Figure 3) show quite different results for these three systems. The point for 4'-CF₃ in the 2-aryl-2-norbornyl case shows an unmistakable deviation of about –0.10 ppm toward a lower frequency isotope shift from the correlation line established for electron donating substituents. A much larger deviation of

–1.25 ppm is seen for the 4'-CF₃ point in the 2-aryl-3-methyl-2-butyl cation series, representing an isotope effect on a rapid equilibrium with a rearranged ion, a conclusion also supported by other evidence. On the other hand, the 4'-CF₃ point in the 1-aryl-1-tolyethyl cations deviates by only 0.02 ppm in the high-frequency direction. This latter deviation is in the same direction and of the same magnitude as in the reference system, the 2-aryl-2-propyl cations, so it likely indicates that there is no structural feature other than those also in the reference system that lends itself to perturbation of its vibrationally averaged character by deuterium substitution.

Isotope shifts in the 2-aryl-2-norbornyl series have been examined in considerable detail,^{14,16} and, for electron withdrawing substituents, there is a clear resemblance to isotope shifts in the 2-methyl-2-norbornyl cation, although isotope shifts at C-2⁺ are much smaller in the aryl series. The isotope shift TIED plots for this system as well as the 2-aryl-2-bicyclo[2.2.2]octyl, 2-aryl-2-bicyclo[2.1.1]hexyl, and 1-aryl-1-cyclopropylethyl cations could be explained by a lowering of the potential energy surface for motion of nuclei toward C–C bridging so that the vibrationally averaged structure becomes slightly bridged as electron demand increases.¹⁹ Isotopic substitution may then alter the vibrationally averaged extent of bridging in the more electron deficient cations, thereby giving a different isotope shift than expected by extrapolation from the less electron deficient cations. The combination of the TIED with NMR isotope shifts appears to reveal the subtle transition from simple hyperconjugation to the point at which geometric distortion toward bridging has observable physical consequences.

1 INTRODUCTION

Nitrogen has two useful nuclei for NMR spectroscopy, ^{14}N and ^{15}N , each with advantages and disadvantages. The drawbacks of these nuclei restricted the use of nitrogen NMR in the early decades of NMR spectroscopy, but Fourier transform spectroscopy, higher field magnets, larger samples, clever pulse techniques, and multidimensional spectroscopy have greatly expanded the use of nitrogen NMR.

The NMR properties of ^{14}N and ^{15}N are given in Table 1. Both nuclei have rather low magnetogyric ratios γ , so their sensitivity to NMR detection is rather low, relaxation processes are rather slow, coupling constants $J(\text{N},\text{X})$ are small and $J(\text{N},\text{N})$ values very small. Working at higher field (B_0) increases the accessibility, the signal intensity increasing as $\gamma^3 B_0^{\frac{3}{2}}$.

The spin- $\frac{1}{2}$ nucleus ^{15}N is now much used in high-resolution work, but its natural abundance is low, 0.36%. Another disadvantage is that $\gamma(^{15}\text{N})$ is negative, so NOE factors are negative, ^{15}N signals becoming more negative with proton decoupling. The maximal proton-induced NOE factor for ^{15}N is -4.93 . A disadvantageous NOE can be removed by the use of paramagnetic additives such as $[\text{Cr}(\text{acac})_3]$.

Much work uses enrichment of ^{15}N , which may not be expensive if nitric acid, ammonium salts, or nitrites can be used as starting materials. With enrichment to 99% the NMR receptivity is six times that of ^{13}C in natural abundance. Sensitivity enhancement by polarization transfer, by INEPT or related methods, is helpful, particularly if there are protons directly attached to the ^{15}N . The gain compared with ^{13}C is now the greater, since $\gamma(^{15}\text{N})$ is smaller than $\gamma(^{13}\text{C})$.

The highly abundant nucleus ^{14}N (99.64%) has nearly six times the receptivity of ^{13}C in natural abundance (1%). Nitrogen-14, however, is quadrupolar ($I = 1$), so that ^{14}N NMR spectroscopy commonly suffers from line broadening and loss of spin-spin coupling due to too-fast relaxation. The ^{14}N quadrupole moment is relatively small, however, and if the local symmetry is high or the sample viscosity low ^{14}N work can be done in high resolution. This possibility is

often overlooked nowadays, although the phenomenon of the chemical shift was uncovered very early on in ^{14}N resonance in an aqueous solution of ammonium nitrate NH_4NO_3 , which gave two sharp lines.¹

Quantitative work in ^{14}N or ^{15}N resonance is difficult because of the multiplicity of factors affecting the signal intensities, and in ^{14}N spectroscopy, the linewidth.

There is now a large volume of work in nitrogen resonance and only key or indicative references can be given. There have been two useful books on ^{15}N NMR spectroscopy.^{2,3} The review literature includes the useful compendia of nitrogen NMR work published at intervals by Witanowski, Stefaniak, and Webb,⁴⁻⁶ annual updates in appropriate chapters of the *Specialist Periodical Reports on Nuclear Magnetic Resonance*,⁷ and several articles.⁸⁻¹⁴ Experimental techniques are described in some detail in by Levy and Lichter,² Martin et al.,³ and von Philipsborn and Müller,¹³ and updates in Volumes 1-23 of *Specialist Periodical Reports on Nuclear Magnetic Resonance*.⁷

Nitrogen NMR spectroscopy affords a variety of information, with the choice of a spin $\frac{1}{2}$ or a quadrupolar nucleus, and an unusual variety of bond types, giving a range of 1350 ppm in chemical shift. Nitrogen forms bonds with all elements except those that are completely inert. Nitrogen can be found in nine stable oxidation states, with bond orders up to three, and coordination numbers up to six, the highest being in metal clusters. Moreover the shifts, coupling constants, and ^{14}N linewidths can be interpreted in terms of bond type, because of the characteristic influences of lone pair and π electrons associated with the observed nucleus, electrons which are of great importance to chemical structure and reactivity.

1.1 Nitrogen Referencing

Nitrogen NMR spectroscopy has suffered from a multiplicity of reference standards,¹⁵ but consensus now favors the use of neat liquid nitromethane as external reference. Table 2 gives standards in the literature. Arguments in favor of nitromethane are that its ^{15}N signal is little affected by proton decoupling, the ^{14}N signal is sufficiently sharp, the neat liquid is accurately reproducible, and it can be obtained enriched with ^{15}N or ^2D with negligible effect on the chemical shift.

Nitrogen referencing should be by substitution. Internal referencing is unsatisfactory because of the magnitude and variety of medium effects for nitrogen (see Section 1.3 below). These are very large when nitrogen carries a lone pair, and can be quite large in the absence of lone-pair electrons if the nitrogen carries π electrons, as in nitromethane, as shown in Table 2. If $[\text{Cr}(\text{acac})_3]$ is used as a relaxation agent, a susceptibility correction, proportional to the concentration of the paramagnetic reagent, is necessary for precise work. The susceptibility shift in an electromagnet in which the field is perpendicular to the NMR tube is half the magnitude and opposite in sign to that in a superconducting magnet.

Ammonia is unsuitable as a reference substance since the nitrogen shift and the magnetic susceptibility are both highly sensitive to hydrogen bonding, and therefore to temperature, pressure, and to the presence of other substances. Ammonia is included in Table 2 as a 'theoretical' reference standard, since the spin-rotation determination of the nitrogen shielding (σ) in the isolated NH_3 molecule¹⁶ forms the basis of an absolute scale for calculated values of σ .¹⁷ Values of the shielding for

other molecules are then obtained from the chemical shift (δ) by use of equation (1).

$$\sigma = -\delta - 135.8 \quad (1)$$

The use of ammonia or ammonium salts as reference material has been favored by those wishing to avoid negative shifts, as achieved by the use of TMS for ¹H, ¹³C, or ²⁹Si. But ammonium salts are subject to medium effects, again because of hydrogen bonding. Table 2 shows that there is a difference of

nearly 7 ppm from the nitrate to the chloride in saturated solutions. The use of Me₄NCl or Et₄NCl, which are less subject to medium effects, has not found favor. Nitrate ion, also, is susceptible to medium effects, which may be large in acidic solution because of equilibria involving nitric acid HONO₂.

Table 2 includes reference standards for solid state work. Ammonium chloride is commonly used for this, and should be the standard of choice.¹⁸ There is a large variation in the NH₄⁺ shift with different anions, particularly oxyanions, because of hydrogen bonding: Table 2 shows a difference of 17 ppm from the nitrate to the chloride.

The publications of Witanowski, Webb, and co-workers,^{5,6} which use the nitromethane standard, give nitrogen shieldings (low frequency positive) rather than shifts (δ), maintaining consistency with their earlier reports when δ and σ had the same sign, before the IUPAC sign convention for δ was adopted in 1972.

1.2 Isotope Effects and Labeling

Nitrogen-14 and ¹⁵N measurements are interchangeable, since primary isotope effects on nitrogen shifts are negligible. Bloch–Siebert shifts, arising from the negative magnetogyric ratio of ¹⁵N, are detectable in double resonance experiments, and corrections may be needed in the determination of accurate values of chemical shifts by homonuclear decoupling experiments.¹⁹

Nearest-neighbor isotope effects are not uncommon. Normally a heavier isotopic substituent increases the nitrogen shielding, with some additivity for multiple substitution. Deuteration increases the nitrogen shielding by about 0.65 ppm per hydrogen replaced in NH₃, cf. 0.5–0.7 ppm in pyridinium ion, amines, or amides. The effects are smaller in NH₄⁺, about 0.3 ppm per hydrogen.²⁰ Equilibrium isotope effects on the nitrogen shift have been reported, arising from the perturbation of tautomeric or hydrogen-bonding equilibria by deuteration.²¹

Neighbor effects of replacement of ¹⁶O by ¹⁸O are small, about 0.15 ppm per oxygen in nitrite ion, or 0.06 ppm in nitrate, but can be useful in mechanistic studies. In the oxidation of ammonia to nitrite by *Nitrosomonas europae*, or of nitrite to nitrate by *Nitrobacter vinogradsky*, the movement of the ¹⁸O label has been monitored by ¹⁵N NMR.²²

Nitrogen-15 labeling for high-resolution NMR, particularly in biomolecules, has the added advantage that the isotope can

be used as a biological tracer. The most stable radioisotope, ^{13}N , has a half-life of only 10 min.

Equilibrium isotope effects can arise unexpectedly in studies of compounds partially enriched with ^{15}N . A doubling of the nitrogen line was observed for the five-coordinate dinitrosyl complex $[\text{RuCl}(\text{NO})_2(\text{PPh}_3)_2]^+$, with 50% enrichment. This complex has one linear and one bent nitrosyl in the solid,²³ and shows bent linear fluxionality in solution.²⁴ ^{15}NO is slightly favored in the linear geometry in the $(^{14}\text{NO})(^{15}\text{NO})$ molecule, giving a slightly higher averaged shielding than the $(^{15}\text{NO})_2$ molecule. Zero-point energies are generally small for nuclei as heavy as nitrogen. This isotope effect is observable because of large differences in stretching frequency and nitrogen shift in linear and bent nitrosyls, arising from the effects of the lone pair on the bent nitrogen.

1.3 Medium Effects

The NMR properties of nitrogen carrying a lone pair are very sensitive to changes of solvent, concentration, counterion, or pH. Nitrogen NMR spectroscopy is thus a useful probe of inter- and intramolecular influences and equilibria. Medium effects on the shielding may be pronounced if hydrogen bonding or acid–base interactions occur, as Table 2 indicates. The shifts are in the same direction as protonation shifts (Section 4.1), though smaller. Hydrogen bonding to a lone pair on nitrogen commonly decreases the nitrogen shielding in saturated groups such as ammonia and alkylamines,²⁵ with sizeable deshielding from gaseous to liquid NH_3 , as from NH_3 to NH_4^+ .²⁶ Nitrogen shielding is increased, however, by hydrogen bonding through hydrogen covalently bonded to nitrogen. The nitrogen shielding in NH_4^+ increases with an increase in the strength of the hydrogen bonding to the anion,²⁷ and is particularly high in anhydrous HF .²⁸ Corresponding results are observed for protonated amines.²⁶ Hydrogen-bonded systems, therefore, show complex behavior, including proton exchange.

For nitrogen in a π -bonded system, as in nitriles RCN , or aromatic azines such as pyridine, hydrogen bonding to a lone pair on nitrogen increases the nitrogen shielding. Again, the shifts are in the same direction as protonation shifts, but smaller in magnitude. Medium effects when the nitrogen carries π but not lone-pair electrons are illustrated by the 9 ppm range shown in Table 2 for the nitrogen shift in nitromethane in different solvents. Four-coordinate nitrogen not bonded directly to hydrogen is relatively insensitive to medium effects, as expected.

Medium effects are observable also in spin–spin couplings to nitrogen because of their sensitivity to the presence of lone pairs.

Nitrogen-14 Knight shifts have been used to study solutions of alkali metals in ammonia²⁹ or methylamine³⁰ which contain solvated electrons.

2 NITROGEN-15 NMR SPECTROSCOPY

Relaxation processes are important to the design of ^{15}N NMR experiments, because of the low natural abundance, one-third of that of ^{13}C , and low NMR sensitivity, one-fifteenth of that of ^{13}C , and because ^{15}N NOE factors are negative.

Figure 1 Dipolar spin–lattice relaxation times T_{1dd} as a function of the effective molecular correlation time τ_c for different field strengths B_0 (T). A field strength of 11.74 T for ^{15}N corresponds to 500 MHz for protons. Values of τ are given in Tables 3 and 4

2.1 Nitrogen-15 Relaxation^{2–7,31,32}

Nitrogen-15 relaxation processes are qualitatively similar to those of ^{13}C in analogous environments, as in $>\text{NH}_2$ and $>\text{CH}_2$. The relative contributions of the possible mechanisms are usually different, because dipolar relaxation by protons is less efficient for ^{15}N than for ^{13}C , since $|\gamma(^{15}\text{N})|$ is only 40% of $\gamma(^{13}\text{C})$. This means that other relaxation mechanisms compete with the dipolar mechanism for ^{15}N . Representative values of relaxation times and NOE factors are given in Table 3, together with examples of particular relaxation mechanisms.

The dipole–dipole (dd) relaxation rate for nitrogen bonded to n_{H} hydrogens is given by equation (2). The relaxation time T_{1dd} depends on the changes in local fields as the molecule tumbles, and is proportional to $(1 + \omega^2 \tau_c^2)$, where ω is the resonance frequency and τ_c is the ‘correlation time’. This is the time the molecule takes to reorient itself in rotational motion, and may take an effective value in view of the complexity of tumbling motions in many molecules or groups, τ_c . Equation (2) assumes sufficient mobility that normal conditions of ‘extreme narrowing’ apply, with $\omega^2 \tau_c \ll 1$.

$$1/T_{1dd} \approx \left(\frac{\mu_0}{4\pi}\right)^2 n_{\text{H}} (\gamma_{\text{N}})^2 (\gamma_{\text{H}})^2 \left(\frac{\hbar^2}{r_{\text{NH}}^6}\right) \tau_c \quad (2)$$

The contribution to the relaxation rate $(T_{1dd})^{-1}$ per hydrogen at a distance of 10 pm is then $5 \times 10^9 \tau_c$. This corresponds to T_{1dd} values of 15–80 s for nitrogen with one attached hydrogen, in small-to-medium-sized molecules in common solvents. Liquid pyrrole has $T_1 = 40 \text{ s}$ ³³ and aqueous acetamide $T_1 = 14 \text{ s}$.³⁴

As molecular tumbling slows down beyond the ‘extreme narrowing’ region, it reaches the Larmor precession frequency below which spin–lattice relaxation is less effective as τ_c increases.³⁵ The value of T_{1dd} falls to a minimum near $\omega \tau_c = 1$ and then increases depending on the field strength B_0 , as shown in Figure 1. There are concomitant changes in the NOE.

Such a decrease in T_{1dd} for longer correlation times is advantageous to the study of biomolecules such as lysozyme, a globular protein of molecular mass 14 600 Da, for which a

^aMeasurements were made at ambient temperatures (300 ± 3 K) if no other temperature is given.

^bValues of τ_c are in ps (10^{−12}s).

^cRelaxation mechanisms are given in decreasing order of their contribution: dd = dipole–dipole (intra- or intermolecular), sr = spin–rotation, (int) = internal, sa = shielding anisotropy, e = electron–nuclear, sc = scalar coupling, pe = proton exchange.

^dTPP is *meso*-tetraphenylporphyrin.

correlation time of 8.5×10^{-9} s was measured in aqueous solution. Lysozyme, hemoglobin, vitamin B₁₂, or transfer-ribonucleic acids could be studied in natural abundance of ¹⁵N at 18.25 MHz (180 MHz for protons).³⁶ Internal motions, such as segmental rocking or spinning of a pendant group such as −NH₃⁺, reduce the effective τ_c for the nitrogens concerned.

Working at higher fields is thus detrimental for biomolecules, since the $T_{1\text{dd}}$ minima shift to smaller values of τ_c with an increase in B_0 (Figure 1).

Unlike T_1 , the transverse (spin–spin) relaxation time T_2 decreases steadily with an increase in τ_c to a limiting value in the solid state determined by dipolar interactions. Uncertainty broadening may be a hazard, since $T_{2\text{dd}}$ has an additional τ_c -dependence which is independent of ω . Deuteration was used to improve ¹⁵N resolution in hemoglobin studies through the γ^2 -dependence of the dipolar relaxation rate.³⁷

The microviscosity η' is important, since the correlation time is proportional to η'/kT . In work with smaller molecules the

relaxation rate may be doubled by the use of more viscous solvents such as dioxan or ethanol, rather than chloroform or acetone. Dipolar relaxation has been speeded up by the use of viscous additives, such as glycerol in aqueous solution, or polystyrene in toluene for organic-soluble molecules.³⁸ Higher macroviscosities are unlikely to broaden the lines by an increase in the transverse relaxation time T_2 since this depends on the microviscosity, which is smaller than the macroviscosity by a factor of six to seven.³³ Cooling is particularly effective as it increases the viscosity (depending exponentially on the temperature) and the sensitivity and the correlation time.

Relaxation times may be quite long in the absence of nearby hydrogen or of alternative mechanisms of relaxation. Neat liquid nitrobenzene and benzonitrile have T_1 values in excess of 400 s, compared with 140 s for aqueous nitrate (Table 3).³⁹ ‘Exposed’ nitrogen, as in a cyano group or in aromatic azines such as pyridine, experiences intermolecular dipolar relaxation

in which T_{1dd} is directly proportional to the distance of closest approach of the hydrogen.

Electron–nuclear relaxation, however, is likely to be present. This is promoted very efficiently by paramagnetic impurities, of iron or nickel for example, to which basic nitrogen is very sensitive. Rigorous purification is necessary for measurements of nitrogen relaxation times,³⁴ although the effects of dissolved oxygen are small.

Paramagnetic additives may be useful for quantitative studies, to quench dipolar relaxation and the NOE.³⁴ Susceptibility corrections may then be necessary for accurate shift measurement (Section 1.1). With $[\text{Cr}(\text{acac})_3]$ there is some hydrogen bonding between hydrogen attached to nitrogen and carbonyl groups in the ligand. Gadolinium complexes such as $[\text{Gd}(\text{acac})_3]$ interact quite strongly with basic nitrogen, and can be used for spin-labeling.

The spin–rotation (sr) mechanism is effective in the relaxation of ^{15}N in small molecules or ions, such as gaseous NH_3 ,⁴⁰ aqueous nitrate or nitrite ion,⁴⁰ or liquid dinitrogen; also in freely rotating substituents, nitro⁴⁰ or nitrite⁴¹ for example (Table 3). The sr mechanism becomes more efficient at higher temperatures, the rate being proportional to kT .

Shielding anisotropy (sa) relaxation is important for linear groups such as $-\text{C}\equiv\text{N}$, as the aqueous ion CN^- ,⁴² in nitriles,⁴⁰ or as a ligand; the same applies to dinitrogen⁴³ (precise work with metal complexes is difficult because of the difficulty in excluding paramagnetic ions). This mechanism is efficient also in planar groups, such as nitro or nitrate, and azine nitrogen as in pyridine (Table 3). The rate is very sensitive to the shielding anisotropy $\Delta\sigma$, being proportional to $(\Delta\sigma)^2$; values of $\Delta\sigma$ are discussed in Section 5. This mechanism is very effective at higher fields, the rate being proportional to B_0^2 . Table 3 shows the increase in relaxation rate with an increase in the applied field for the cyanide ion and nitrobenzene.⁴⁴

In some molecules all three mechanisms (sa, dd, and sr) are operative, as for pyridine and *trans*-azobenzene. Another mechanism of importance for ^{15}N is afforded by proton exchange (pe) in hydrogen-bonded systems, magnetization being transferred by the migrating proton. Table 3 includes an example of the fast relaxation of ^{15}N by scalar coupling to fast-relaxing ^{14}N in $^{14}\text{N}^{15}\text{N}$ gas.⁴⁵

In the solid state, the dipolar relaxation of ^{15}N is fast in NH_4Cl .⁴⁶ Relaxation is faster still in *meso*-tetraphenylporphyrin (TPP), in which two hydrogens exchange between the central four nitrogens, a process long known in solution. Studies of T_1 and NOE show that the unprotonated nitrogen relaxes by the sa mechanism, by dipolar interaction with the protons on the other nitrogens, and through proton exchange.⁴⁷

2.2 Nitrogen-15 NOE Factors⁴⁸

If ^{15}N is wholly relaxed by $^{15}\text{N}/^1\text{H}$ dipolar interactions, the NOE factor (η), with broadband proton decoupling, is given by equation (3):

$$\eta_{\text{max}} = \gamma(^1\text{H})/2\gamma(^{15}\text{N}) = -4.93 \quad (3)$$

The negative sign corresponds to inversion of the signal. (Note the use of the symbol η for the NOE factor and also for the viscosity.) The net enhancement is then -3.93 , better than the ^{13}C value of 2.99. There is a further gain in signal height from the collapse of multiplets.

The NOE factor observed depends on the proportion of the relaxation that takes place by $^{15}\text{N}/^1\text{H}$ dipolar interactions:

$$\eta_{\text{obs}} = (I - I_0)/I_0 = -4.93(T_1)_{\text{obs}}/T_{1dd} \quad (4)$$

If this proportion is small the signal intensity (I) is diminished and the signal vanishes if the proportion is 20% ($I = 0$, $\eta_{\text{obs}} = -1$).

Five mechanisms have been identified by which ^{15}N signals can be lost on proton decoupling.⁴⁹ The dipolar process diminishes when more efficient modes of relaxation are possible, as in the presence of paramagnetic compounds, or averaging by fast chemical exchange. Table 3 shows many molecules for which the full NOE factor -4.93 is not achieved under the conditions of the experiment.

The diminution in T_{1dd} as correlation times τ_c increase beyond the ‘extreme narrowing’ limit, illustrated in Figure 1, also diminishes the NOE, the more so at higher resonance frequencies ω . With large or highly associated molecules, the NOE may be unfavorable,⁵⁰ and working at higher fields disadvantageous. The maximal NOE factor shrinks from -4.93 to -0.12 , and the signal is annulled for a correlation time of 1 ns at 11.7 T (500 MHz for protons). The NOE may be removed by gated decoupling or by paramagnetic additives, promoting electron–nuclear relaxation.

The NOE has various uses, i.e. as a measure of molecular mobility or dynamics, in spectral assignment, and to locate spin labels. A disadvantage is the difficulty in using signal intensities in quantitative work.

2.3 Nitrogen-15 Sensitivity Enhancement

Nitrogen-15 sensitivity is enhanced by the use of larger samples, higher fields, lower temperatures, and proton decoupling and the NOE, if favorable. Valuable enhancements are obtained by the use of special pulse sequences transferring polarization (magnetization) from a more sensitive nucleus, usually the proton, to which the ^{15}N nucleus is coupled. A 10-fold enhancement is given by the $\gamma(^1\text{H})/\gamma(^{15}\text{N})$ ratio, and the sign of γ is now immaterial. Further amplification may be gained by faster pulsing, allowed by the faster proton relaxation.

In the liquid phase magnetization can be transferred via spin–spin coupling to protons, if this is resolvable. Such methods have the advantage over NOE enhancement of not requiring the relaxation mechanism to be dipolar. They include J cross polarization (JCP), selective polarization transfer (SPT), ‘insensitive nuclei enhanced by polarization transfer’ (INEPT), ‘distortionless enhancement by PT’ (DEPT), and developments of these.^{2,3,7,51} In $>\text{NH}$ systems, as in bilirubins for example,⁵² measurements may be made in this way in natural abundance of ^{15}N . Longer-range couplings also may be used in azaaromatic or peptide systems. The methods are used to determine coupling constants and their signs, to establish connectivities, to distinguish nitrogens bearing different numbers of hydrogens, to correlate signals of different nuclei, to investigate relaxation processes, and to measure relaxation times.

Multiple quantum methods involving a double transfer of magnetization, $^1\text{H} \rightarrow ^{15}\text{N} \rightarrow ^1\text{H}$, provide substantial improvements in ^{15}N sensitivity because of the detection in proton spectra. They are increasingly used to correlate ^1H and ^{15}N shifts in two-dimensional (2D) spectra through spin–spin

coupling pathways.⁵³ Polarization transfer from ^{15}N to ^1H decreases ^1H sensitivity, but has been used in 2D spectroscopy to assign all the ^{15}N signals of a labeled tRNA by heteronuclear decoupling difference spectroscopy.⁵⁴

A variety of 2D, 3D, and even 4D experiments in correlation spectroscopy (COSY) are now being used to correlate ^{15}N , ^{13}C , and ^1H resonances.⁵⁵ A 3D experiment may correlate ^{15}N resonances with those of differently connected protons, as in $^{15}\text{N}^1\text{H}-\text{C}^1\text{H}$ groups in biological systems. 4D techniques are being used in protein research, as in the correlation of ^1H , ^{13}C , ^{15}N , and ^{13}CO resonances in calmodulin.⁵⁶

Comparable experiments have been performed in which magnetization is transferred from ^2D , ^{19}F , or ^{31}P to ^{15}N . The faster relaxation of the deuteron, by the quadrupolar mechanism, compared with the proton, may outweigh the disadvantage of the relatively small magnetogyric ratio of ^2D . In the solid state, cross polarization (CP) is used to transfer magnetization via dipolar couplings. (See *Organic Chemistry Applications*.)

3 NITROGEN-14 NMR SPECTROSCOPY

The ^{14}N quadrupole moment is relatively small ($Q = 0.0199 \times 10^{-28} \text{ m}^2$) and a large volume of NMR work has been done in ^{14}N resonance, particularly when ^{15}N spectroscopy was less accessible. In some respects, ^{14}N work is coming into its own again as modern techniques turn the ^{14}N nuclear quadrupole interaction to advantage, to spread nitrogen spectra over a large range, more than compensating for quadrupolar line broadening.^{57,58}

Nitrogen-14 linewidths vary quite widely, depending on the local electronic symmetry of the ^{14}N nucleus and its mobility. High-resolution spectroscopy is possible if the local electronic symmetry and the mobility are both high. Sharper lines may be obtained if the sample viscosity can be reduced by the use of higher temperatures or more mobile solvents (Section 3.2). Fast relaxation may be advantageous in allowing rapid pulsing. The variability of ^{14}N linewidths must be taken into account in quantitative work.⁵⁹

^{14}N NMR is a useful probe of molecular dynamics, because of the sensitivity of the linewidth to local motions. Nitrogen-14 induced relaxation of protons in peptide ($-\text{NH}-\text{CO}-$) groups in protein backbones which exchange with water protons is of importance to proton NMR tomography.⁶⁰

3.1 Nitrogen-14 Quadrupolar Relaxation⁶¹

The ^{14}N linewidth $W_{1/2}$, the width at halfheight of the (Lorentzian) line or component of a multiplet, is proportional to the relaxation rate and to the square of the nuclear quadrupole coupling constant (NQCC) χ [equation (5)]. The quadrupolar relaxation time T_q is equal to $T_1 = T_2$ in the extreme narrowing regime ($\omega^2\tau_c \ll 1$), i.e. for mobile species.

$$\pi W_{1/2} = 1/T_q = \frac{3}{8}\chi^2(1 + \eta^2/3)\tau_q \quad (5)$$

where

$$\chi = e^2qQ/\hbar \text{ (in radians)} \quad (6)$$

In equation (6), eq (or more precisely eq_z , where $|q_z| \geq |q_x| \geq |q_y|$) is the electric field gradient (efg) at the nucleus. The quantity η is now the asymmetry parameter, equal to $(q_x - q_y)/q_z$. Linewidths are very sensitive to χ but less sensitive to η , since $\eta \leq 1$ by definition. The quantity $\tau_q = \tau_c$ is the effective correlation or reorientation time of the ^{14}N quadrupole. NQCC values are obtained from the NQR spectroscopy of solids, from the microwave spectroscopy of gases, and by NMR methods.⁶² Values of χ are usually similar in the liquid or solid phase of a particular species, and are about 15% greater in the gas phase.

The ^{14}N electric field gradient is largely determined by the disposition of the valence p electrons. In highly symmetric environments, in which there is no static efg, quadrupolar relaxation is mediated by collisional and vibrational distortion of molecules or ions.^{63,64} Although the ^{14}N quadrupole moment is relatively small, relaxation of ^{14}N is almost invariably by the quadrupolar mechanism because of the χ^2 -dependence of the rate. Even in the highly symmetric location in solid NH_4Cl , the dipolar relaxation mechanism is observed only below 220 K.⁶⁵ Above 220 K, rotation of the ammonium ion in the lattice switches the efg at the ^{14}N nucleus, so relaxing the nuclear electric quadrupole and the nuclear spin. In aqueous solution, ^{14}N in NH_4^+ shows zero NOE because of transient efgs arising from the buffeting by solvent dipoles.⁶⁶ In paramagnetic cyano complexes $\text{K}_3[\text{M}(\text{CN})_6]$, where $\text{M} = \text{Cr}, \text{Mn}, \text{Fe}$, the ^{14}N relaxation was found to be wholly quadrupolar, even though the nitrogen shifts were determined by the contact interaction.⁶⁷

3.2 Nitrogen-14 Linewidths

Table 4 lists the ^{14}N linewidths, relaxation times, NQCC values χ , and correlation times for a range of compound types, grouped by the coordination number of the nitrogen and in approximate order of increase in linewidth. Nitrogen-14 lines may be quite sharp, with χ values of 1 MHz or less, if the nitrogen is in a highly symmetrical location, as in NH_4^+ ,⁶¹ NF_4^+ (tetrafluorammonium),²⁸ or tetraalkylammonium (R_4N^+) species.⁶⁸ Nitrogen-14 spectra were obtained in the first measurement of interstitial nitrogen, in the trigonal prismatic clusters of cobalt and rhodium⁶⁹ $[\text{M}_6\text{N}(\text{CO})_{15}]^-$, before the ^{15}N lines were obtained with 97% enrichment. For the rhodium cluster there was some resolution of three lines of the septet, with $^1J(\text{Rh}, ^{14}\text{N}) \approx 4 \text{ Hz}$. The ^{14}N and ^{15}N lines were similar in width for the cobalt cluster because of line broadening by the ^{59}Co quadrupole and unresolved coupling.

Nitrogen-14 lines are sharp also if the nitrogen is centrally placed in linear groups such as the nitronium ion (NO_2^+)^{6a} or azide ion (N_3^-),⁷⁰ or in trigonal planar groups such as nitrate ion,⁷¹ all highly mobile in solution.

Linewidths may be small if the substituents on nitrogen do not differ greatly in electronegativity, as in the linear molecules NVO^{72} and isonitriles RNC .^{73,74} Compared with the nitrate ion, broader lines are observed for ethyl nitrate, nitromethane,^{75,76} or NOF_2^+ ,²⁸ broader still for pyridine N -oxide,⁷⁷ PhNO_2 ,⁷⁸ or dimethylamide,⁷⁹ more bulky molecules. The line is very broad for the oxygenated nitrogen in azoxybenzene, which carries a π bond, a single bond, and a double bond.⁸⁰ The fluorammonium ion, NH_3F^+ , with substituents of very different electronegativity, gives a broad

^bObserved linewidths may contain unresolved couplings.

^cViscosity.

^dValues of τ_q are in ps (10⁻¹² s); compare the values measured in ¹⁵N resonance (Table 3). Where three values are given, these correspond to $\tau_{x,y,z}$, where the *x* direction is that of the axial bond to nitrogen and the *y* direction is in the molecular plane.

line²⁸ with some broadening being due to the hydrogen bonding in the HF solvent.

Long-chain tetraammonium species give very broad lines. The ¹⁴N relaxation properties of Me₃N groups have been used to study reorientational motion. In the surfactants C_nTAC and C_nTAB, the two motions reported in Table 4 are rotation within a micelle and a slower diffusional motion.^{81,82} In biomolecules, the choline Me₃N headgroup is a useful probe of orientation, as in studies demonstrating a phase transition in the phospholipid sphingomyelin, from bovine brain membrane,⁸³ or changes in phosphatidylcholine in the presence of anaesthetics.⁸⁴

The efg and the linewidth are greatly increased by the presence of a lone pair on the nitrogen. This electronic charge is close to the nucleus, even closer if the substituents on the nitrogen are highly electronegative as in NF₃, in which the ¹⁴N NQCC is very large.²⁸ Linewidths are sizeable generally for pyramidal nitrogen, as in amines,^{85–88} and for bent (two-coordinate) nitrogen, as in organic isocyanates,⁸⁹ nitrites,⁷⁵ and pyridine.⁹⁰

The lone pair on terminal (one-coordinate) nitrogen is less effective in line broadening because of the axial symmetry.

Again, linewidths increase with an increase in electronegativity of the nearest neighbor, from dinitrogen^{42,47} to nitrile species RCN^{91–95} and to the nitrosyl ion NO⁺.²⁸ In dinitrogen oxide, N₂O, the ratio of the linewidths for the two nitrogens in solution is as expected from the NQCCs determined by microwave spectroscopy in the gas phase.⁷³

Similarly, protonation or coordination reduces NQCC values. They are reduced also by delocalization of a lone pair in conjugated systems, as in pyrrole,⁹⁶ and delocalization which flattens a pyramidal group, or increases the bond angle for two-coordinate nitrogen. The effects of bond-angle distortion are evident for nitrogen in three- to seven-membered rings.⁶⁹ Hydrogen bonding to a lone pair on nitrogen slightly reduces the NQCC, while hydrogen bonding of a lone pair on nitrogen has the opposite effect, as shown by pyrrole in pyridine.⁹⁶

Certain ligands in metal complexes are usefully studied by ¹⁴N NMR study, so long as the molecules are not too bulky or associated. Linear ligands may give sharp lines because of the axial symmetry at nitrogen. Sharp lines were observed for the imido (nitrene) ligand (=NR) in *trans*-[WF₄(NMe)L] complexes,⁹⁷ and shifts were measurable for

the imido complexes of Ta, W, and Os, even with quite bulky R groups such as SiMe₃, helped by internal mobility.⁹⁸ Despite the ⁹⁵Mo quadrupole, ¹⁴N lines were readily resolved in dialkyldithiocarbamate complexes of molybdenum with NO or NS coligands,⁹⁹ and ⁹⁵Mo–¹⁴N couplings were resolved for η⁵-cyclopentadienyl complexes with NO and CO ligands.¹⁰⁰ Quite sharp lines were observed in PdCN^tBu complexes.¹⁰¹ The kinetics of electron transfer reactions between ferricyanide and ferrocyanide ions in aqueous solution were studied by ¹⁴N linewidth measurements.¹⁰²

Otherwise, ¹⁴N lines are usually broad for ligating nitrogen, whether with bulky (e.g. phosphine) coligands, of the difference in electronegativity of the nearest neighbors: examples in Table 4 are the ammine and ethylene diamine complexes of cobalt.^{103,104}

There is a direct dependence of ¹⁴N linewidth on the sample viscosity for a wide range of molecules. Linewidths may be halved by the use of diethyl ether solvent instead of chloroform, or acetone instead of water. Fluoronitrogen compounds are readily studied by ¹⁴N NMR because of their high mobility.²⁸ Resolution of *J* couplings to quadrupolar nuclei has been achieved for super- or near-critical fluids in standard thick-walled tubes, including ¹⁴N¹⁴N and ¹⁴N¹⁷O couplings in liquid N₂O.¹⁰⁵

Warming a sample is particularly helpful, the viscosity decreasing exponentially with increase in temperature. The rotational correlation time for a spherical molecule is given by the Stokes–Einstein–Debye theory as

$$\tau_c = V\eta/kT \quad (7)$$

where η is the viscosity and V is the molecular volume, equal to $4\pi r^3/3$.³³ equation (7) gives a correlation time of 1 ps for a molecule of radius 1 Å at 300 K for $\eta = 1$ cP. Observed rotational motions are faster by a factor of about 6, and a microviscosity η' that is one-sixth of the bulk viscosity is envisaged.

Direct dependence on viscosity breaks down for molecules that are small, linear, or flat, rotating or librating between neighboring molecules. Molecules rotating relatively freely in the liquid phase have a reduced temperature dependence of τ_c , according to equation (8), where I is a moment of inertia:

$$\tau_c = \frac{1}{2}(\pi I/3kT)^{1/2} \quad (8)$$

Quadrupolar relaxation in ionic solutions⁶⁷ is mediated by the rotations of ions and solvent dipoles, by collisions, and by molecular vibrations. In mobile solutions, with $\omega^2\tau_c \ll 1$, the relaxation rate is given approximately by equation (9):

$$\pi W_{1/2} = 1/T_q = 8\pi(\beta e q Q/\hbar)^2 \left[\mu_s^2 c_s r_0^{-5} \tau_s + \sum_i z_i (3a_i^3)^{-1} c_i \tau_i \right] \quad (9)$$

Terms with the subscript *s* give the effects of solvent dipoles, and with the subscript *i*, the effects of ionic charges. The *c* terms are concentrations, r_0 and a_i are distances of closest approach, μ_s is the dipole moment, z_i are ionic charges, and τ_s , τ_i are the respective correlation times. Further terms are needed for hydrogen bonding or exchange processes. If D₂O replaces H₂O, the motions are slowed by the higher mass and stronger hydrogen bonds.

The electric field gradient is now amplified by a factor given by equation (10), as

$$\beta = P(1 - \gamma_\infty) \quad (10)$$

where $P = (2\epsilon + 3)/5\epsilon$ is the polarizability of the solvent, with dielectric constant ϵ . The quantity $(1 - \gamma_\infty)$ is the Sternheimer antishielding factor which represents the distortion of the inner electron shells by electric field gradients in the valence shell. Experimental determinations are rare: values of 9 and 22–26 have been determined for $(1 - \gamma_\infty)$ in solid NH₄Cl, compared with a calculated (ab initio) value of 6.8.¹⁰⁶

4 PATTERNS OF NITROGEN SHIFTS

The large literature of nitrogen shifts is reviewed regularly.^{6,7} Nitrogen shifts in diamagnetic compounds cover a range of 1350 ppm, over three times the carbon range. The comparison with carbon is helpful since carbon shielding patterns are well known. The greater range for nitrogen arises from its greater electronegativity, and its ability to carry lone-pair electrons with s character, which carbon does very rarely.

The major determinants of nuclear magnetic shielding are demonstrated by expressions such as equation (11) for the paramagnetic term σ_p , which dominates the nitrogen shift in diamagnetic compounds. The negative sign of σ_p (ppm) represents deshielding, so the shift δ increases with the absolute magnitude of σ_p .

$$\sigma_p \approx -\frac{\mu_0}{4\pi} \frac{e^2}{2m_e^2} \langle r^{-3} \rangle_{2p} \frac{\langle 0 | \mathbf{L}^2 | 0 \rangle}{\Delta E} \quad (11)$$

Equation (11) embodies an ‘atom-in-a-molecule’ approximation^{107,108} in a simplified form. It does not give accurate results, but is useful in showing the three factors of importance to the shielding. The first is the radial term $\langle r^{-3} \rangle_{2p}$, where r represents the radius of the 2p electron on the observed atom. The value of the radial term for the free atom, which can be viewed as a scaling factor for the shifts of a particular nucleus, is twice as large for nitrogen (2.46 a.u.) as for carbon (1.23 a.u.);¹⁰⁹ the more electronegative atom holds its valence p electrons closer to the nucleus, giving a larger paramagnetic shift.

The second factor is the term in $\mathbf{L}^2$ representing the angular momentum which allows the electronic charge to circulate in a magnetic field, so as to reinforce the field. This paramagnetic circulation opposes the free diamagnetic circulation, which is fully realized only in the free atom or round the axis of a linear molecule. The paramagnetic circulation requires an asymmetry of charge in the valence shell of the observed atom, i.e. in the p orbitals of a second-row element such as carbon or nitrogen. The angular momentum term in equation (11) is analogous to the *Q* terms in the theory of Karplus and Pople, expressing imbalance of charge, or the *P_u* term in the theory of Jameson and Gutowsky.¹⁰⁹ Electronic asymmetries which potentiate the paramagnetic circulation are small in highly symmetric environments, as in CH₄ or NH₄⁺, but may be large for two-coordinate nitrogen carrying a lone pair.

The third factor, ΔE , is an effective excitation energy for the paramagnetic circulation. This can be considered to arise from virtual excitations of p → p type, which may be $\pi \leftrightarrow \sigma$

(i.e., $\pi \rightarrow \sigma^*$ or $\sigma \rightarrow \pi^*$), $n \rightarrow \pi^*$, or $\sigma \rightarrow \sigma^*$ from one bond to another, as the magnetic field mixes into the ground state those excited states which allow circulation of charge. Excitation energies vary more widely for nitrogen than for carbon, since lone pair (n_N , or nonbonding) electrons afford a high lying HOMO, and LUMOs involving nitrogen are low lying because of the electronegativity of nitrogen. The frontier orbitals in question are those appropriate to charge rotation (e.g. $n_N \rightarrow \pi^*$, but not $\pi \rightarrow \pi^*$), and the terms HOMO and LUMO may represent more than one High lying Occupied MO, or Low lying Unoccupied MO, when more than one excitation contributes significantly to the deshielding. These magnetic-dipole-allowed excitations are normally forbidden in the electronic spectrum. They are weakly allowed in $n_N \rightarrow \pi^*$ excitations in which there is a component of the $s \rightarrow p$ type, giving the well-known long wavelength bands of the azo chromophore, for example. More precise formulations of equation (11) embody a summation over the magnetically active excitations.

Equation (11) shows that the deshielding (δ) is the greater the closer the paramagnetic circulation to the nucleus (the more electronegative the substituents), the smaller the energy ΔE of the virtual excitation (the HOMO–LUMO or frontier orbital gap for charge circulation), and the greater the imbalance of charge in the valence shell. All three factors are important when extremes of high or low shielding are observed.

In isoelectronic (isostructural) locations, the shieldings of nitrogen and carbon, indeed the shielding tensors, show similar shielding patterns, with scaling according to the radial factors. Similar patterns are evident in Figure 2, which compares nitrogen and carbon shift ranges for some standard bond types. Figure 3 gives nitrogen shift ranges for compounds formed with main group elements, and Figure 4 is a comparable chart for ligands in transition metal complexes.

4.1 Nitrogen Compared with Carbon

In Figure 2 the nitrogen and carbon charts are scaled by the 2:1 ratio of the radial terms $\langle r^{-3} \rangle_{2p}$ for the free atoms, to make the shifts readily comparable. A major difference between the nitrogen and carbon charts is the extension of the nitrogen range to lower shielding for π -bonded nitrogen carrying a lone pair of electrons, as in azo (diazene) groups $RN=NR$ or nitroso compounds RNO .

High carbon or nitrogen shielding is observed in CH_4 or NH_4^+ because of the electropositive substituent hydrogen ($\langle r^{-3} \rangle_{2p}$ is small), the high electronic symmetry in the valence shell (the angular momentum term is small), and the high energy of the $\sigma \rightarrow \sigma^*$ excitations (ΔE is large).¹¹⁰ The energy of the $n \rightarrow \sigma^*$ excitation is also high in ammonia, and the lower nitrogen shielding in NH_4^+ compared with NH_3 is largely attributable to the positive charge on the nitrogen, increasing the radial term and excitation energies. Nitrogen shifts are found to correlate with the atomic charges estimated for nitrogen in amines, nitro compounds, isonitriles, and azines.¹¹¹

Nitrogen is strongly deshielded as an interstitial atom in the metal cluster carbonyls such as $[Rh_6N(CO)_{15}]^-$, a trigonal prism, and $[Ru_6N(CO)_{16}]^-$, which is octahedral.⁷⁰ The interstitial carbon in the corresponding clusters is even more strongly deshielded, as shown in Figure 2. The

deshielding is unexpected in view of the high symmetry and the electropositive and heavy neighbors. Carbon in the corresponding clusters is even more strongly deshielded. Indeed, the deshielding increases with compression of the interstitial atom in the cluster, as observed in some other kinds of cages.¹¹²

The nitrogen shifts in alkylamines and hydrochlorides can be expressed by additive substituent parameters,¹¹³ as for carbon in alkanes. For nitrogen shifts, as for carbon shifts, the increments for each C_α or C_β substituent arise from inductive effects, while the increments for C_γ substituents arise from steric and conformational effects. Substituent parameters have been developed for other compound types,^{2,3} including peptides, but correlation spectroscopy is now used to assign nitrogen resonances.

Lower shielding is generally observed in multiply bonded compared with singly bonded compounds, because of the lower electronic symmetry of the observed atom when π and σ bonds are present and the lower energies of $\pi \leftrightarrow \sigma$ in comparison with $\sigma \rightarrow \sigma^*$ excitations. Figures 2–4 show that quite high shielding is observed for nitrogen as the central atom in a linear group, as in $MeNC$, NNO , or NO_2^+ , or carbon in $MeCN$, NCO^- , or CO_2 . The shielding is relatively high because of the free diamagnetic circulation about the axial direction, as in the noble gas compounds $RC\equiv N-XeF^+$, measured in ^{14}N resonance,¹¹⁴ and $HC\equiv N-KrF$.¹¹⁵

The nitrogen shielding in comparable groups decreases with increasing electronegativity of the neighbor, or with an

Figure 2 Comparison of nitrogen and carbon shifts

Figure 3 Ranges of nitrogen shifts in compounds with main group elements

increase in the positive charge on the ion. Lower shielding may be observed for terminal atoms in linear groups, as in $\text{MeCN} > \text{N}_2 > \text{NO}^+$, or $\text{MeNC} > \text{CN}^- > \text{CO}$.

Figure 2 shows the comparability of the carbon and the nitrogen shielding in isoelectronic pairs such as CH_4 and NH_4^+ , CO (or CN^-) and NO^+ , or CO_3^{2-} and NO_3^- , even for pairs which are not isostructural such as C_2H_6 and N_2H_4 since the lone-pair excitation energies in hydrazine are rather high. The shielding in comparable compounds decreases from single (e.g. $\text{H}_2\text{N}-\text{NH}_2$) to triple ($\text{N}\equiv\text{N}$) to double bonds ($\text{RN}=\text{NR}$) in nitrogen as in carbon resonance. This is the sequence of decrease in symmetry of the local electronic charge (and increase in the NQCC, as illustrated in Table 4) and of decreasing excitation energies.¹¹⁶

In the $n \rightarrow \pi^*$ excitation, charge circulates from the p component of the lone pair into the π^* orbital. The $n \rightarrow \pi^*$ excitation energies are low for diazenes $\text{RN}=\text{NR}$, particularly in extended conjugated systems as in azo dyes.¹¹⁷ The $n \rightarrow \pi^*$ excitation energies and nitrogen shieldings are particularly low for nitroso compounds RNO and nitrosyls NOX . All three factors in equation (11) are operative: the bent nitrogen carrying a lone pair is highly anisotropic, $\langle r^{-3} \rangle_{2p}$ is large because of the electronegativity of oxygen, ΔE is very low since the π^* LUMO is low (because of the electronegativity of oxygen), and the nitrogen lone pair HOMO is raised by the presence of lone-pair electrons on the oxygen.

When excitation energies are small, linear δ/λ correlations may be observed between the chemical shifts δ and the wavelength λ of the low-energy absorption band in the electronic

Figure 4 Ranges of nitrogen shifts in metal complexes

spectrum. Such correlations are well known for organic and inorganic compounds with $n_N \rightarrow \pi^*$ absorption: for carbonyl compounds RCHO or RCOR' in carbon resonance, and in nitrogen resonance, for nitrosyl compounds NOX and RNO,¹¹⁸ azo (diazene) compounds XN=NX and RN=NR,¹¹⁹ diazo compounds YNN,¹²⁰ etc. The nitrogen shielding decreases as the $n_N \rightarrow \pi^*$ band moves to longer wavelengths, from the colorless oxo/fluoro compounds NOF, FNNF, etc., to the compounds with less electronegative substituents, such as PhNO, *t*-BuNO, or Me₃SiN=NSiMe₃ which are blue, and the 1,1-diazenes R₂NN which are purple.¹²¹ In $n_N \rightarrow \pi^*$ chromophores, the nitrogen shift δ and $\lambda(n_N \rightarrow \pi^*)$ both increase in the sequence N=C < N=N < N=O of increase in the electronegativity of the partner in the double bond, lowering the π^* relative to the n_N orbital and increasing $\langle r^{-3} \rangle_{2p}$ for the nitrogen.

4.2 Protonation Shifts

Protonation of the singly bonded nitrogen in ammonia or amines deshields the nitrogen by up to 20 ppm. The deshielding is largest in ammonia in which the charge is strongly localized. Because of the relatively small protonation shifts in amines, there are similar shift relationships for amine nitrogen and alkane carbon in corresponding environments, depending on connectivity, although the groups are not isostructural. Amines which are branched at the α -carbon show small increases in nitrogen shielding on protonation.

Since nitrogen is strongly deshielding by $n \rightarrow \pi^*$ circulations, the effects of protonation of nitrogen in a π -bonded system may be large. Protonation of pyridine increases the nitrogen shielding by about 100 ppm, as the lone-pair electrons on nitrogen are strongly stabilized by the formation of a bond to hydrogen. The radial term $\langle r^{-3} \rangle_{2p}$ is not greatly increased by the positive charge, which is delocalized. Large effects may be observed in metal complexes. Protonation of

dinitrogen attached to tungsten to form the (linear) diazenido ligand, and then the hydrazido(2-) ligand, increases the shielding of the β -nitrogen by 135 and then 55 ppm:¹²² $W-N\equiv N \rightarrow W-N=NH \rightarrow W=N-NH_2$. Protonation shifts of 200 ppm are observed for the doubly bent diazenido group $Pt(II)-N=NPh$ to give a hydrazido(1-) ligand, $Pt-NH=NPh$.¹²³

An exception which proves the rule is the deshielding of nitrogen by ca. 100 ppm on protonation of the cyclic anion formed by deprotonation of 2,4,6-trimethylpyridine.¹²⁴

4.3 Nitrogen NMR Criteria of Structure

The relationships illustrated in Figures 2–4 allow some generalizations on the structural determinants of nitrogen shieldings, in advance of more rigorous discussion of the shielding tensor.

1. In groups which may be bent or linear at nitrogen, the nitrogen is deshielded as the bond angle decreases. The deshielding on bending is the greater, the greater the deshielding in the linear group: thus, bent nitrogen in azides is still quite highly shielded.¹²⁵ Deshieldings are greater in aromatic azines and azoles, and may be greater still in triazenes, as in the $(Ts-NNN-Ts)^-$ ion (Ts = tosyl), in which the central nitrogen is deshielded by 286 ppm compared with the central nitrogen in azide ion, NNN^- .¹²⁶ The difference in nitrogen shift is small for linear and bent imido ligands $M=NR$,¹²⁷ but large in diazenido ligands $M-N=N$ which are bent at the ligating nitrogen.¹²⁴ The nitrosyl group shows large deshieldings. The bent nitrogen in the *N*-nitrosamine Me_2NNO is deshielded by 300 ppm compared with the central nitrogen in nitrous oxide, N_2O , and the nitrogen is deshielded further if the group is distorted from planarity.¹²⁸ Deshieldings up to 800 ppm are reported for metal nitrosyls in the bent compared with the linear ligand,¹²⁹ with smaller shieldings for smaller MNO angles.¹³⁰ Reactions which involve the shift of a d-electron pair onto ligating nitrogen, allowing the metal to accept an incoming ligand and the nitrogen to coordinate a Lewis acid, are readily monitored by nitrogen NMR.]
2. In groups which may be pyramidal at nitrogen carrying a lone pair, or flat, with π delocalization of the lone-pair electrons, the nitrogen is deshielded the flatter the group, as noted early on in substituted anilines.^{2,3} Planarity allows $\pi \leftrightarrow \sigma$ paramagnetic circulations of lower energy than $n_N \rightarrow \sigma^*$ circulations in the pyramidal group. In the planar hydrazido(2-) ligand $M=N-NH_2$, the nitrogen shift (ca. -230 ppm¹³¹) shows significant deshielding compared with hydrazines (ca. -320 ppm), being comparable with amide shifts (cf. -265 ppm for formamide).
3. Protonation and deprotonation shifts have considerable diagnostic value in structural studies. Hydrogen bonding to a lone pair on nitrogen leads to smaller shifts in the same sense. Hydrogen bonding of attached hydrogen gives nitrogen shifts in the opposite sense. Tautomeric and other acid-base systems involving nitrogen are thus well studied by nitrogen NMR methods, with the information from the shifts, ^{14}N linewidths, ^{15}N NOE, and couplings.
4. Coordination shifts may be comparable to protonation shifts. Thus, coordination of BH_3 or BMe_3 to ammonia or alkylamines deshields the nitrogen by a small amount, and

coordination to π -bonded nitrogen increases the shielding markedly, as by 74 ppm when pyridine forms $py \cdot BH_3$. Coordination to transition metals is a more complex question (Section 4.5).

4.4 Nitrogen Bonded to Heteroelements

Figures 3 and 4 show high shielding for carbon or nitrogen singly bonded to boron,¹³² silicon, phosphorus,¹³³ etc., or to transition metals in ammine complexes. These elements are less electronegative than nitrogen. Nitrogen is strongly deshielded in singly-bonded compounds with fluoronitrogen compounds by 370 ppm for liquid NF_3 compared with NH_3 , or 290 ppm for NF_4^+ compared with NH_4^+ .²⁸ Because of the extreme electronegativity of fluorine, its effects as a substituent often have diagnostic value, and have been called (per)fluoro effects in photoelectron and electronic spectroscopy.

In a comparison of similar $N-X$ compounds, the nitrogen shift ranges show periodic trends reflecting the inductive effects of the heteroelement. The nitrogen shielding decreases across the row of the heteroelement, e.g. from $B-N$ to $N-O$ and from $Si-N$ to $N-Cl$, with an increase in the electronegativity of X ; and increases down the group of the neighbor, with a decrease in the electronegativity of X , an increase in polarizability and relativistic effects, and with heavy atom neighbors.

Fluoro effects provide extreme examples, as in the σ -fluoro effects already described. These, and π -fluoro effects, are used in photoelectron and electronic spectroscopy for assignments to σ or π orbitals. Fluorination strongly stabilizes the σ -orbital manifold, of which the lone-pair orbital forms part. The stabilization is less for the π -orbital manifold, in part due to repulsion of π electrons by lone-pair electrons on fluorine. Although nitrogen is strongly deshielded in NF_3 and NF_4^+ compared with NH_3 and NH_4^+ , nitrogen shielding is significantly increased on fluorination of azabenzenes and other planar species (cf. NOF , NO_2F , and N_2F_2).¹³⁴ π -Chloro effects are similar, and smaller.

4.5 Coordination Shifts in Metal Complexes

Coordination shifts from the free ligand to the complex are illustrated by a comparison of Figures 3 and 4, and in Figure 4 itself, since the shift for the free ligand is indicated.

Coordination shifts are usually small in the higher shielding ranges, and smaller for p-block than for d-block metals. On coordination to a transition metal, the nonbonding electrons on nitrogen are stabilized by bond formation, this tending to increase the nitrogen shielding, but low-lying orbitals may then become available to the paramagnetic circulation on ligating nitrogen.

Nitrogen NMR is a criterion of the mode of coordination of ambidentate ligands. Nitrogen is more shielded in $M-NCS$ than in $MSCN$ or in the free NCS^- ion.¹³⁵ Similarly, in the covalent azides $XN_\alpha N_\beta N_\gamma$, N_α is the most highly shielded nitrogen with N_β being buffered from the effects of coordination.¹³⁶

Relatively low shielding is observed for ligating nitrogen in doubly bonded groups such as hydrazide(2-), $M=N-NH_2$, and for π -acceptor ligands such as $NCMe$, N_2 , NO , NS , etc.

The importance of the ligand field splitting to the nitrogen shift is shown by the periodic dependence on the transition metal and by *trans* effects.¹³⁷ These influences are magnified if nitrogen is close to the metal, as in nitrido complexes,¹³³ and for bent or bridging nitrido or nitrosyl ligands.

Trans influences may parallel substituent effects in arenes, such as the increase in nitrogen shielding in anilines, pyridines, and benzonitriles with *para*-substituents which are π donors (and the deshielding if nitrogen with π acceptors). In linear nitrosyl or diazenido complexes, the shielding of ligating nitrogen is increased by *trans*-donors such as OH, and decreased by *trans*-acceptors such as CN or NCMe. The strength of binding of the *trans*-ligand is also significant, since the $d\sigma$ -orbital splitting is larger with softer ligands for metals in low oxidation states. Such correlations include other physical properties such as IR stretching frequencies, reflecting back-bonding to acceptor ligands such as N₂, or redox potentials.

Interest in nitrogen fixation processes has stimulated the study of the dinitrogen ligand in complexes of molybdenum and related metals, and of ligands on the reduction pathway, diazenido, hydrazido, hydrazinium, imido, etc. Nitrogen NMR spectroscopy can usefully distinguish terminal and bridging, or linear and bent ligands, and monitor protonation reactions.

5 NITROGEN SHIELDING TENSORS

More rigorous consideration of the factors determining nitrogen NMR shifts requires a knowledge of the shielding tensor, preferably in conjunction with theoretical calculations. Shielding tensor components have been measured for a number of nitrogen bond types, including ligands in metal complexes. There has been much interest in groups of biological importance, in peptide or imino links for example, in which nitrogen shielding tensors give useful information on the effects of protonation and hydrogen bonding. Other articles discussing nitrogen shielding tensors in biomolecules are given at the end of this section.

Nitrogen tensors resemble those for carbon or phosphorus in isoelectronic and isostructural locations, with scaling by the respective radial factors $\langle r^{-3} \rangle_{np}$ which are in a 2:1 ratio for nitrogen and carbon, as discussed in Section 4.^{109,110} Nitrogen shielding patterns are more closely related to those of phosphorus than of carbon, since the nitrogen and phosphorus valencies are closer, as are the scaling factors, since the ratio of $\langle r^{-3} \rangle_{2p}(\text{N})$ to $\langle r^{-3} \rangle_{3p}(\text{P})$ is 1:0.7.

A major factor for many nitrogen tensors is the presence of lone pair (n_N) electrons on the nitrogen which are strongly directional. The lone-pair axial direction then determines the principal axis system, and major deshieldings are observed for axes which mix n_N and π^* orbitals, following the arguments given in Section 4. Similarly, the nitrogen shielding tensor is a criterion for the bending of two-coordinate nitrogen and the flattening of three-coordinate nitrogen. Tensor measurements, combined with theoretical studies, can frequently throw light on the nature of the bonding.

5.1 Experimental Techniques

The spin-rotation interaction, measured as fine structure in the microwave spectra of gases, has given ¹⁴N tensor

information for NH₃,¹⁶ N₂O,¹⁴² HCN,¹⁴³ and PN¹⁴⁴ (Tables 5 and 6). Tensor measurements have been made on oriented single crystals of glycylglycine · HCl · H₂O^{145,146} and L-histidine · HCl · H₂O in ¹⁵N resonance, and some nitrates in ¹⁴N resonance (Table 7). Most measurements, however, are made on powdered material by ¹⁵N MAS or CP MAS techniques, and/or powder lineshape analysis on a static sample. Some anisotropies have been measured in liquid crystals (MeNC, MeCN, N₂O) and some by relaxation methods (PhNO₂, pyridine).

For some molecules or groups, the orientation of the shielding tensor in the molecular frame is obvious from the chemical structure, and for some it has been established by single crystal measurements. For some others, the orientation has been determined by concurrent measurement of dipolar interaction between ¹⁴N or ¹⁵N with ¹H, ²H, ¹³C, ³¹P, or other nuclei.^{140,145,147} Theoretical calculations, also, may help in the assignment of the axial directions.

Tables 5–7 give the principal components as absolute shieldings σ , with $\sigma_{33} > \sigma_{22} > \sigma_{11}$, and $\sigma_{\text{iso}} = \sigma_{\text{tr}} = (\sigma_{11} + \sigma_{22} + \sigma_{33})/3$. The shieldings are obtained from the chemical shift, δ , with neat liquid nitromethane as standard, according to equation (1), using the absolute scale¹⁹ based on the spin-rotation measurement for NH₃, according to which nitrogen in neat liquid nitromethane has shielding $\sigma = -135.8$:

$$\sigma = -135.8 - \delta(\text{MeNO}_2) \quad (12)$$

Some authors use a liquid ammonia standard, for which the nitrogen shieldings are 244.6 ppm at ambient temperatures and 240.6 at -50°C .¹⁷ Some others use solid NH₄Cl as the reference material, with $\sigma(\text{N}) = 202.5$.

The tensor properties given in Tables 5–7 are the span $\Omega = \sigma_{33} - \sigma_{11}$ and the skew $\kappa = 3(\sigma_{22} - \sigma_{\text{iso}})/\Omega$.^{148,149} For axial tensors, $\Omega = \sigma_{\parallel} - \sigma_{\perp}$ and $\kappa = \pm 1$. The parameters Ω and κ avoid ambiguities that have arisen with the traditional parameters,¹⁵⁰ the shielding anisotropy $\Delta\sigma$ and asymmetry η . For these, the ordering of the σ_{11} , σ_{22} , and σ_{33} axes depends on the ordering of the absolute values of the differences of the tensor elements from σ_{iso} . Some authors have followed the ‘traditional’ order σ_{33} , σ_{22} , and σ_{11} ,¹⁴⁵ while some use the numerical order σ_{33} , σ_{22} , and σ_{11} . In any case, the σ_{33} and σ_{11} axes have to be interchanged for those members of an extended series of compounds which have $\sigma_{22} < \sigma_{\text{iso}}$, as compared with those with $\sigma_{22} > \sigma_{\text{iso}}$. Such series include metal nitrosyls in nitrogen resonance, as described in Section 5.5, or organic carbonyl compounds in carbon resonance.¹⁵¹

Several authors¹⁵² have used the relative magnitudes of the principal components to define the axes as here, rather than relative magnitudes of the absolute values of the differences from σ_{iso} as in the ‘traditional’ definition. The use of the skew parameter κ rather than the asymmetry parameter η preserves sign information, since on the traditional definition $0 \leq \eta \leq 1$ and $\eta = 0$ for axial symmetry whether $\sigma_{\parallel}$ is greater or less than $\sigma_{\perp}$. The skew κ , however, is +1 for $\sigma_{\parallel} > \sigma_{\perp}$ and –1 for $\sigma_{\parallel} < \sigma_{\perp}$.

5.2 Singly Bonded Nitrogen

Shielding tensors are given in Table 5 for nitrogen in ammonia and some derivatives. Although distortion of an oxyanion such as nitrate by hydrogen bonding to the

^a Assumes glycine zwitterion reference has $\delta(\text{N})$ −350 ppm.

ammonium ion has been observed in the nitrogen shielding tensor, the ammonium cation gives a symmetric tensor, as for near-tetrahedral symmetry and reorientational motion such as the switching in NH_4Cl (Section 3).

The shielding tensor for ammonia is unusual in having $\sigma_{\parallel} < \sigma_{\perp}$ ($\kappa = 1$) and a small span, 40.3 ppm.¹⁶ Ammonia is unusual also in the substantial *decrease* in the nitrogen shielding on protonation, as discussed in Section 4. In ammonium salts, the NH_4^+ nitrogen shielding decreases with a decrease in strength of the hydrogen bond to the counteranion (i.e., with a decrease in the electronegativity of the anion), increasing the positive charge on nitrogen.^{153,154} The deshielding is related to contraction of the 2p N orbitals from NH_3 to $\text{NH}_3 \cdots \text{H}^+$, with a strongly hydrogen-bonding anion, and then to NH_4^+ , as the counterion hydrogen bonds more weakly.

Much smaller deshieldings are observed on the protonation of amines, in which cationic charge is less localized on the nitrogen. R-NH_3^+ tensors, of which a number have been measured in biomolecules such as histidine or glycine, have a very small span, about 10 ppm.

There is little change in the NH_3 isotropic shift on formation of ammine ligands in *cis*- $[\text{Pt}^{15}\text{NH}_3)_2(\text{SCN})_2]$, with weak bonding to the metal. There is some increase in span of the NH_3 tensor, but a considerable decrease in the skew, in this planar complex. The σ_{33} component is sensitive to a change in location in the crystal.¹⁵⁵

Combined shielding tensor and dipolar shift measurements have been used to characterize NH protons and measure the bond distances in polycrystalline and amorphous solids of biological importance, in ^{14}N ¹⁵⁶ and in ^{15}N ¹⁵⁷ resonance. Protonated imine nitrogen is discussed under the heading of the parent compound.

5.3 Nitrogen in Linear Groups

The principal components of nitrogen shielding tensors for linear systems are given in Table 6. Maximal shielding is observed for the C_{∞} axis with its largely diamagnetic circulation. Most values of the parallel shielding $\sigma_{\parallel}$ are in the range 300–370 ppm, resembling the (diamagnetic) shielding of atomic nitrogen, 325 ppm.¹⁵⁸

The parallel shielding, 350 ppm in MeCN ,¹⁵⁹ decreases by 80–100 ppm when the π electrons can delocalize into an aromatic ring, as in the iminophosphenium cation¹⁶⁰ and benzonitriles.¹⁶¹ Interesting σ -inductive and π -conjugative effects of a 4-substituent in the benzene ring on the cyano-nitrogen shielding tensor have been monitored for benzonitriles $4\text{-Y-C}_6\text{H}_4\text{-C}\equiv\text{N}$ with $\text{Y} = \text{OMe}, \text{NMe}_2, \text{NO}_2, \text{CN}, \text{Cl}, \text{Br}, \text{F}, \text{Me}, \text{CMe}_3$, and NMe_3^+ . Some of the largest changes in tensor components relative to $\text{Y} = \text{Me}$ are produced by a positively charged substituent NMe_3^+ , which decreases σ_{33} in the $\text{C}\equiv\text{N}$ by 11 ppm (and σ_{11} and σ_{22} by 7 and 16 ppm, respectively). Similarly the parallel shieldings in dinitrogen $\text{N}\equiv\text{N}$ ¹⁶² are reduced by 51 and 13 ppm on coordination to molybdenum.

The perpendicular tensor components arise from $\sigma \leftrightarrow \pi$ (i.e., $\sigma \rightarrow \pi^*$ and $\pi \rightarrow \sigma^*$) circulations, and for terminal nitrogen from $\text{n}_\text{N} \rightarrow \pi^*$ circulations also. The separation of the σ_{11} and σ_{22} components by around 30 ppm in the benzonitriles and iminophosphenium ion reflects conjugation with the aromatic ring. In the benzonitriles the separation is largest (41 ppm) with the π -donor Me_2N as the 4-substituent.

For terminal nitrogen in the linear groups the perpendicular shielding ($\sigma_{\perp}$) is highest in NNO and lowest for PN : the latter has the longest bond (so orbital splittings are smaller) and phosphorus is the least electronegative partner. For N_2O , ab initio calculations using the LORG method¹⁶³ show comparable (major) contributions to σ_{p} for the terminal nitrogen from its lone pair and the NN bond, and for the central nitrogen from the NN and NO bonds.

For two-coordinate nitrogen, the perpendicular shielding decreases from MeNC ¹⁶⁴ to ArNP^+ and to $[\text{Mo}(\text{dppe})_2(^{15}\text{N}_2)_2]$,¹⁶⁵ as the orbital splittings decrease.

5.4 Nitrogen in Planar Systems

Principal values for nitrogen tensors in planar systems are given in Table 7. The highest shielding and a small span are observed for three-coordinate nitrogen bound only to carbon and hydrogen, in amides or peptides, azinium nitrogen in the five-membered rings in tryptophan, and L-histidine $\cdot \text{HCl} \cdot \text{H}_2\text{O}$ and iminium groups.

5.4.1 Peptides and Amides

Table 7 shows the similarities of the components in an amide, asparagine,¹⁶⁶ in which the σ_{33} axis bisects the NH_2 group, in Nylon-6,¹⁶⁷ and in peptides.^{139–168} Concurrent observations of $^{13}\text{C}^{15}\text{N}$ and $^{15}\text{N}^1\text{H}$ dipolar interactions in L-(1- ^{13}C)alanyl-L-(^{15}N)alanine confirmed earlier conclusions on the orientation of the nitrogen tensor.¹⁴² The axis of lowest shielding σ_{11} is in the amide plane perpendicular to the CN bond, allowing relatively low-energy $\text{CN } \sigma \leftrightarrow \pi$ circulations. Unusually (in contrast to carbon tensors in peptides, and to carbon and nitrogen tensors in aromatic and other delocalized systems), the high-shielding axis σ_{33} is in-plane in the CN bond direction; the intermediate axis σ_{22} is perpendicular to the plane. These directions are approximate, varying somewhat in different peptides. In glycylglycine and related peptide links, there is, accidentally, near-axial symmetry, with $\kappa \approx +1$, and the σ_{11} axis is at 99° to the CN bond.

The σ_{11} component is the least variable because of constancy of the CN bond, although sensitive to the geometry of the hydrogen bonding, the σ_{11} axis being nearest to the $\text{N-H} \cdots \text{O}$ direction. The σ_{11} axis is smaller in an α -helix than in a β -sheet, and is sensitive also to the handedness of the helix. The out-of-plane component σ_{22} reflects the conformation and secondary structure, being larger in a β -sheet than in an α -helix.¹⁶⁹ The σ_{22} component is unusually low and σ_{33} unusually high ($\kappa = -0.3$) in the link to proline, in which the nitrogen is in a saturated five-membered ring, although the alanylalanine isotropic shift is maintained in alanylproline.¹⁷⁰ The importance of lattice effects is shown by differences of isotropic shifts in solution.

5.4.2 Azines, Azinium

Despite the chemical importance of aromatic azines, few of their nitrogen tensors have been studied to date. Table 7 includes ranges of principal components observed for protonated nitrogen in five-membered rings of biological interest, in tryptophan^{159,171} and in histidine.¹⁵⁹ These components are comparable to the values for pyridine.¹⁷² In delocalized ($\text{p}\pi$)

systems, the out-of-plane axis shows the highest shielding (σ_{33}) in carbon resonance, depending on the relatively high-energy $\sigma \rightarrow \sigma^*$ excitations in the plane. This is borne out in nitrogen resonance, as in the protonated imidazole ring in histidine hydrochloride: the σ_{33} axis is almost perpendicular to the ring and the σ_{11} axis almost along the NH bond. Similar components are observed for tryptophan, studied as the hydrochloride, and in vivo in a bacteriophage that orients in the magnetic field.

Comparison with pyridine shows the major increases in σ_{11} and σ_{22} on protonation. In pyridine, the σ_{11} axis is tangential to the ring, mixing n_N and π^* orbitals, and the σ_{22} axis radial, this shielding being mediated by $\sigma \leftrightarrow \pi$ circulations. The value of σ_{22} for pyridine resembles that of $\sigma_{\perp}$ in MeCN, rather than MeNC (Table 6).

5.4.3 Planar Systems with CN, NN, NP, and NO Bonds

The cyano and phosphonium groups in ArCN and ArN⁺P can be described as planar, since conjugation with the aromatic system removes the axial symmetry of the CN and PN groups, although these bonds are triple and form the σ_{33} axis.

In the compounds with bent two-coordinate nitrogen, benzyldeneaniline,¹⁷³ (*E*)-acetophenone oxime,¹⁷⁴ *trans*-azobenzene,¹⁷⁵ and 4-dimethylaminonitrosobenzene,¹⁷² dipolar chemical shift measurements support the σ_{22} direction as bisecting the angle at nitrogen (effectively along the lone-pair axis). The σ_{11} axis is that of the $n_N \rightarrow \pi^*$ circulation. The nitrogen tensors show that the σ_{11} component in the planar groups becomes more strongly negative as the π^* LUMOs come down in energy relative to the n_N orbital, with increasing electronegativity of the partner in the double bond from C=N to N=N and to N=O. Very low shieldings are $\sigma_{11} = -789$ ppm for azobenzene (which is red-orange, with $n_N \rightarrow \pi^*$ absorption at 448 nm) and -1457 ppm for 1,4-dimethylaminonitrosobenzene¹⁷⁴ which is green.

In *trans*-azobenzene there are two molecular sites, differing in the span (925 and 880 ppm) and skew (0.392 and 0.325), while the isotropic shift is maintained. The azo group (CNNC) is effectively planar and centrosymmetric in both sites with the same N=N bond length, but the torsion angles NNCC are significantly different, 17° and <10°. (The low barrier to twisting of the phenyl group is shown by the torsion angle of 30° observed in the gas phase by electron diffraction.)

The nitrate ion is characterized by a small span.^{176,177} The σ_{22} component is less negative in nitrobenzene because of the smaller paramagnetic contribution of the CN bond, and more negative when there is a lone pair on nitrogen in the plane as in the bent nitroso group in Me₂NC₆H₄NO. The nitrite ion is intermediate as expected.¹⁷⁸

A sizeable (σ_{11}) deshielding is associated with the $n_N \rightarrow \pi^*$ circulation in bent nitrosyl groups, and to a lesser extent in NO₂[−] for which LORG calculations¹⁷⁶ show that the contribution to $\sigma_{P_{iso}}$ of the n_N electrons on the symmetry axis exceeds that of the NO bonds. In contrast is the high shielding in the nitroso dimer PhN(O)N(O)Ph, which is a diazene bis-*N*-oxide: the σ_{11} and σ_{22} values match those in nitrobenzene, and σ_{33} matches $\sigma_{\perp}$ in the nitrate ion.¹⁷⁹

The effects of protonation of π -bonded nitrogen, and of variations in the strength of hydrogen bonding to a counterion, have been studied in the Schiff base (aldimine) retinylidene-Buⁿ-(¹⁵N)imine, RB. This models the light-harvesting membrane protein bacteriorhodopsin (bR) which was measured

with selective ¹⁵N,¹³C-enrichment. Protonation of bR with a strong acid (HCl) increases σ_{11} by 327 ppm and σ_{22} by 115 ppm (Table 7). From HCl to HBr to HI and to weak organic acids (carboxylic acids or phenols), σ_{11} and σ_{22} show small increases with strengthening of the N–H⁺ bond (σ_{11} and σ_{22} being linearly related) while σ_{33} is little changed. The values for dark-adapted bR resemble those of RBH⁺ when very weakly hydrogen bonded.¹⁸⁰

The ¹⁵N and ¹³C studies demonstrate the major contribution of the counterion to the opsin shift in the photocycle. Color changes in the protein with pH correlate with changes in the ¹⁵N shielding, which increases as the neutral purple membrane (568 nm) becomes the acid blue membrane (600 nm), reverting with the change to the acid purple membrane (565 nm); the weak hydrogen bond in the protein weakens in the blue form. The opsin-induced red shift, therefore, arises from interaction of an electronegative group in the protein with the Schiff base end of the chromophore, *cis*–*trans* isomerization being excluded by the comparison with the 13-*cis*,15-*syn*-bR₅₄₈ tensor.

5.5 Linear and Bent Nitrosyls in Metal Complexes

The nitrogen shielding tensor is a useful criterion for the bending of the nitrosyl ligand, and many of the nitrosyls studied are unstable in solution. In five-coordinate {MNO}⁸ complexes (i.e., with eight (d + n) electrons), the metal may have a trigonal pyramidal coordination sphere (d⁸) with the nitrosyl linear (NO⁺), or else a square-pyramidal coordination sphere (d⁶) with bent apical nitrosyl (NO[−]), and similarly for the diazenido ligand (N=NR⁺ and N=NR[−]). The first measurement of a nitrogen tensor in a metal complex was of [RuCl(¹⁵NO)₂(PPh₃)₂][BF₄],²³ which has one linear and one bent nitrosyl in the solid state and shows fast bent–linear fluxionality in solution.²⁴

Table 8 lists the nitrogen tensor components for linear nitrosyl ligands, which may be compared with those of NNO and the bent nitrosyl in [RuCl(¹⁵NO)₂(PPh₃)₂]⁺ in Table 9. In the linear ligand, as in [Fe(CO)₃(¹⁵NO)][−],¹⁸¹ the $\sigma_{\parallel}$ values are significantly more negative than is expected for the free ligand NO⁺. This reflects greater back-bonding to the nitrosyl compared with the carbonyl ligand, which is a useful model with many ¹³C tensors having been measured.¹³⁸ The perpendicular components in the nitrosyls are somewhat more negative than in NNO, and more negative in a bis-nitrosyl than in a mononitrosyl, for the same metal. Bis-nitrosyls are usually *cis* and the neighboring nitrosyls interact, to bend slightly. [Fe(NO)₂ (cystine)] is an example of a compound for which the nitrogen shielding tensor has given the structure: the solid is amorphous and insoluble, but the nitrogen tensors clearly show the nitrosyls to be linear and probably *cis*.¹⁸²

The ruthenium complex with one bent and one linear nitrosyl shows that bending of the nitrosyl makes a large paramagnetic contribution to σ_{11} and a significant contribution also to σ_{33} . These effects can be seen to some degree in the bis-nitrosyls in Table 8, the adjacent linear ligands interacting to produce a small degree of bending.

Table 9 gives the tensor properties of bent nitrosyl ligands, and Figure 5 shows the structures of the complexes.^{182–184} In some complexes the planarity of the basal ligand is maintained by chemical bonding or strong hydrogen bonding. In the

^aBridging NO.

others, the nitrogen tensor components are a useful proof of structure since all have the pyramidal structure, but not all the bis-chelate compounds are constrained to coplanarity. An example is the $[\text{Co}(\text{NO})(\text{rsal})_2]$ series, of which the parent complexes $[\text{Co}(\text{rsal})_2]$ have tetrahedral coordination. For $[\text{CoCl}_2(^{15}\text{NO})(\text{PPh}_3)_2]$, which is fluxional in solution, the tensor properties show the nitrosyl to be bent in the solid.

All three tensor components for bent nitrosyls show significant deshielding compared with those in linear nitrosyls. The σ_{11} values are strongly negative and very variable. The bridging nitrosyl in $[\text{Ru}_3(\text{CO})_{16}(\mu_2\text{-NO})]^-$ shows a relatively high σ_{11} shielding as the nitrogen is now three-coordinate, Ru_2NO ; the σ_{33} shielding is unexpectedly high.

The apical nitrosyls show a remarkable variation in the span and skew, while the isotropic shift δ is maintained at 680–780 ppm, except for higher shielding with S_4 ligation of cobalt. All components reflect significant mixing of the nitrogen and the cobalt paramagnetic circulations (more precisely, the out-of-plane components of the ligand field circulations deshielding cobalt), as observed in solution studies showing some correlation of ^{15}N and ^{59}Co shifts.¹²⁹

Because of the large effects of relatively small changes in small excitation energies, sensitivity may be expected to the internal MNO geometry and to the conformation of the nitrosyl relative to the ligands in the basal plane. The ligand field

is also sensitive to the location of cobalt (usually above the plane), to the ligation, and to the bite of the chelate ligands. The nitrosyl oxygen may lie over a gap between two chelate ligands as in $[\text{Co}(\text{NO})(\text{ketox})_2]$ and $[\text{Co}(\text{NO})(\text{esal})_2]$, or over an electron acceptor such as a phosphine. It lies over the ethylene bridge in $[\text{Co}(\text{NO})(7\text{-mesalen})]$ and $[\text{Co}(\text{NO})(\text{salen})]$, over a linear nitrosyl in $[\text{RuCl}(^{15}\text{NO})_2(\text{PPh}_3)_2]^+$, over sulfur in $[\text{Co}(\text{NO})(\text{S}_2\text{CNMe}_2)_2]$, over oxygen in $[\text{Co}(\text{NO})(\text{acacen})]$, and over nitrogen in $[\text{Co}(\text{NO})(\text{benacen})]$.

The remarkable variation of the tensor components in Table 9 may involve the effects of the conformation of the nitrosyl relative to the ligand field of the coligands in the plane, and the small barrier to rotation of the nitrosyl which is disordered in many of the crystal structures. Torsional variation could account for compensatory effects in the tensor components, with σ_{22} and σ_{33} decreasing as σ_{11} increases, decreasing the span while maintaining the isotropic shift.

A low torsional barrier and the sensitivity of the projecting nitrosyl to intermolecular forces are shown by the unusual nitrogen tensors observed for $[\text{Co}(^{15}\text{NO})(\text{TPP})]$ at ambient temperatures, which demonstrate swinging or spinning of the nitrosyl in the solid state.¹⁸⁴ The isotropic shift is that of a bent nitrosyl, but from room temperature down to 220 K the tensor shows axial symmetry ($\kappa = 1$) and a small span, 242 ppm. The full span of 1655 ppm and nonaxial symmetry appeared when

Figure 5 Structures of complexes with a bent apical nitrosyl ligand

the sample was cooled to 200 K, with little change in isotropic shift.

No intermediate rate behavior was observed and differential scanning calorimetry showed a phase transition in the solid at 206.7 K with $\Delta H = 649 \text{ J mol}^{-1}$. The lattice presumably relaxes at this temperature, allowing the nitrosyl to revolve about the C_4 axis at higher temperatures. A CoNO angle of 127° calculated from the tensor measurements agrees with the value of $\leq 128.5^\circ$ estimated from the X-ray diffraction study at ambient temperatures.¹⁸⁵ This showed a fourfold disorder of the nitrosyl depicted in a many-headed ‘hydra’ diagram, the oxygen lying in the gap between two porphin nitrogens. This picture, therefore, is that of a swinging nitrosyl.

5.6 Theoretical Calculations of Nitrogen Shielding Tensors

Several ab initio methods are now being used with some success for the calculation of shielding tensors,¹⁴⁹ including the local-origin methods IGLO¹⁸⁶ and LORG.¹⁸⁷ Agreement with experiment is good for singly bonded molecules with high electronic excitation energies. It is less good when excitation energies are low, and for species with multiple bonds and lone pairs on the nucleus in question. This presents hazards in nitrogen studies, particularly in groups containing oxygen.

IGLO calculations¹⁸⁸ of nitrogen shieldings for a range of compounds have been analyzed in terms of the contributions from bonding electrons and lone pairs. The calculations show very small deshielding in NH_3 , and greater deshielding

on substitution of H by Me, then NH_2 , OH, or F, with strong effects on the lone-pair contribution. The Cl and Ph groups behave as weakly electronegative substituents. Strong deshielding is found when the nitrogen is doubly bonded, with some exaggeration of the paramagnetic effect in the calculation. In aromatic azines, the calculations reflect the deshielding observed from pyrrole (with no $n \rightarrow \pi^*$ state) to pyridine and to pyridazine (with two adjacent nitrogens).

In molecules with low excitation energies the inclusion of electron correlation to second order, as in the SOLO (second-order LORG) method,¹⁸⁹ produces considerable improvement, as in a study of nitrite and nitrate ions.¹⁷⁸ There is further improvement with the inclusion of six surrounding cations for nitrite ion. The decrease in shielding with lengthening of the NO bonds, or, for nitrite, with an increase in the bond angle, shows that vibrational corrections are also significant.

6 PATTERNS OF NITROGEN SPIN-SPIN COUPLINGS

Figures 6–8 give ranges of one-bond J couplings between ^{15}N , ^1H , and ^{13}C in functional groups. Couplings to nitrogen are more commonly measured in ^{15}N than in ^{14}N resonance because of ^{14}N line broadening by quadrupolar relaxation. A large number of ^{14}N couplings have been measured, however, under favorable conditions of high local electronic symmetry and short correlation times (Section 3.2). All four ^{14}N couplings could be measured with accuracy in the linear cation $\text{RC}\equiv\text{NXeF}^+$.¹¹⁴ More measurements of ^{14}N and other quadrupolar nuclei, such as the two $^{14}\text{N}^{17}\text{O}$ couplings measured in N_2O , are expected with the growing use of supercritical fluids.¹⁰⁵

Values of $J(^{14}\text{N}, \text{X})$ are 30% smaller than $J(^{15}\text{N}, \text{X})$ values and opposite in sign, following the respective values of the magnetogyric ratios γ for ^{14}N and ^{15}N , as shown in equation (13):

$$-^n J(^{15}\text{N}, \text{X}) = 1.403 ^n J(^{14}\text{N}, \text{X}) = ^n K(\text{N}, \text{X}) \times h\gamma_{\text{N}}\gamma_{\text{X}}/4\pi^2 \quad (13)$$

Here K is the reduced coupling constant, which is independent of the nucleus, and n is the number of bonds through which the nuclei are coupled. The quantity J is in Hz and K is in $\text{N A}^{-2} \text{ m}^{-3}$. Couplings to nitrogen are relatively small since the γ values are rather small. Couplings producing a 1:1 doublet in ^{15}N resonance produce a 1:1:1 triplet in ^{14}N resonance because of the three combinations of orientations for a nucleus with $I = 1$.

Figure 6 shows that $^1J(\text{N}, \text{H})$ values are negative, becoming more negative with increasing s character in the N–H bonding orbital, from sp^3 hybridization of the nitrogen as in NH_4^+ or amines, to sp^2 as in the pyridinium ion pyH^+ , and to sp as in the nitrilium ion $\text{RC}\equiv\text{NH}^+$. Linear equations have been given which relate the coupling to the percentage s character in the nitrogen orbital.^{197–199} These equations, and a corresponding equation relating $^1K(\text{C}, \text{N})$ to the product of the percentage s character in the nitrogen and carbon orbitals,¹⁹⁷ fail when there are lone pairs with s character on one or both of the coupled nuclei, and may fail in the presence of multiple bonding.

Values of $^1J(\text{N}, \text{H})$ are reduced significantly in absolute magnitude by the presence of (s-type) lone pair electron density on nitrogen. The smallest couplings involve bent nitrogen in ketimines $\text{R}_2\text{C}=\text{NH}$ or diazenides $\text{M}-\text{N}=\text{NH}$,

Figure 6 Ranges of $^1J(^{15}\text{N}, ^1\text{H})$ values

and those for amines or ammonia are small. Similarly, $^1J(\text{N}, \text{H})$ values increase significantly in magnitude with the loss of lone pair electron density on nitrogen by coordination, delocalization (as in aniline), or protonation. They also increase with hydrogen bonding of the nitrogen, and may be solvent dependent. NH couplings may be lost through chemical exchange, and rigorous purification may be needed in order to observe them.

Couplings are increased in magnitude regardless of sign by the presence of more electronegative substituents on a coupled nucleus. Values of $^1J(\text{N}, \text{H})$ are quite large in the $-\text{C}(\text{O})\text{NH}-$ link, present in peptides, amides, lactams, ureas, and Nylons. The values are larger if the proton is *trans* to oxygen but decrease with a departure from planarity at the nitrogen, with the development of a lone pair.

Signs reported for $^1J(^{15}\text{N}, ^{13}\text{C})$ are also normally negative, with some exceptional small positive values which change sign and increase in absolute magnitude on protonation. In pyridine $^1J(^{15}\text{N}, ^{13}\text{C})$ is +0.6 Hz, changing to -11.7 Hz on protonation and to -15.2 Hz in pyridine *N*-oxide.²⁰⁰ Figure 7 shows that $^1J(^{15}\text{N}, ^{13}\text{C})$ values become more negative from azomethines $\text{R}_2^{13}\text{C}=\text{N}^{15}\text{R}$, with a lone pair on the nitrogen, to amines, and to ynamines $\text{RC}\equiv^{13}\text{C}-^{15}\text{NR}'_2$, in which there is no lone pair on the nitrogen. Such changes may thus be stereochemically diagnostic. In oximes $\text{R}_2\text{C}=\text{NOH}$, in which the nitrogen is pyramidal, the *Z* form is flatter than the *E* form thus reducing *cis* repulsions and, as expected, $^1J(^{15}\text{N}, \text{C})$ is more negative

for the *Z* than for the *E* form. Values of $^1J(^{15}\text{N}, \text{C})$ are quite large in magnitude for pyrroles, in which the nitrogen 'lone pair' is of the p type.

Signs reported for $^1J(^{15}\text{N}, ^{15}\text{N})$ couplings are negative, but many are still unknown so the values in Figure 8 have been plotted regardless of sign. Values of $^1J(^{15}\text{N}, ^{15}\text{N})$ are generally small in magnitude when terminal nitrogen is involved, as in diazo compounds R_2N_2 , N_2O , or dinitrogen ligands. Similarly in azides $\text{RN}_\alpha\text{N}_\beta\text{N}_\gamma$, which are bent at N_α , $^1J(^{15}\text{N}, ^{15}\text{N})$ couplings are much smaller for $\text{N}_\beta\text{N}_\gamma$ than for $\text{N}_\alpha\text{N}_\beta$. The couplings are very small, around 1 Hz, in arene-diazonium compounds ArNN^+ . Many of these values are the result of complex effects of lone pairs and multiple bonds. Somewhat larger values are observed when the nitrogen is bonded to oxygen.²⁰¹

Geminal couplings $^2J(^{15}\text{N}, \text{H})$ and $^2J(^{15}\text{N}, \text{C})$ are usually negative and relatively small. They become more negative if the nitrogen carries a *cis* or proximate lone pair, the more so if this lies in the NXH or NXC plane. Thus $^2J(^{15}\text{N}, \text{H})$ is -3 Hz in pyH^+ but -11 Hz in pyridine. Such values are diagnostic of the geometry, and of protonation or coordination of the nitrogen. Couplings of the type $^2J(^{15}\text{N}, ^{15}\text{N})$, as observed in nucleotides for example, show similar lone-pair effects. Values of $^3J(^{15}\text{N}, \text{H})$ also are increased in magnitude by a *cis* or proximate lone pair on the nitrogen as in oximes, and the magnitude increases with protonation of the nitrogen as

Figure 7 Ranges of $^1J(^{13}\text{C}, ^{15}\text{N})$ values

in pyridine. Values of $^3J(^{15}\text{N}, \text{C}, \text{C}, \text{H})$ often show a Karplus-type dependence on the dihedral angles, and are of use in conformational studies of peptides in which the 3J values may be larger than 2J values of similar type.²⁰²

6.1 Contact, Orbital, and Spin–Dipolar Contributions to the Coupling^{190, 194, 203–206}

Nitrogen couplings are sensitive to the s,p character of the bonding and to the presence and orientation of a lone pair with s character on the nitrogen, because the Fermi contact interaction of s electrons with the nucleus is usually the most important contribution to the coupling. The coupling patterns are usefully interpreted by means of the Dirac vector model²⁰⁷ of the contact interaction (even though this model is incomplete, and sometimes misleading). Electrons in a bonding pair with antiparallel spins $\alpha\beta$ correlate their motions so that if the α spin is near one nucleus the β spin is near the other. For a nucleus with positive γ , the electron–nuclear configuration is more stable when the spins are antiparallel since $\gamma\epsilon$ is negative. The values of $^1J(\text{X}, \text{Y})$, therefore, are

normally positive, the difference hJ between the energy states with antiparallel and parallel spins being positive by definition. Corresponding values for $^1J(^{15}\text{N}, \text{Y})$ are negative since $\gamma(^{15}\text{N})$ is negative. The coupling increases in absolute magnitude with an increase in s character in the orbitals forming the bond between the coupled nuclei. Similarly, couplings are increased by the presence of more electronegative substituents on a coupled nucleus, since these demand greater p character, leaving more s character in the bond which is the coupling pathway.

Lone pair electron density on either or both of the coupled nuclei alters this picture. Figure 8 shows that if one of the coupled nuclei carries a lone pair, $^1J(\text{N}, \text{C})$ diminishes in absolute magnitude by an amount that increases with the s character of the lone pair, e.g. from RNH_2 , sp^3 , to pyridine, sp^2 (though not to nitriles RCN , sp). As demonstrated in calculations of C–N and N–N couplings, the contribution to the Fermi contact term J^{fc} from the lone pair electrons is opposite in sign to that of the bonding electrons, since the nonbonding MO is antibonding with respect to the coupling pathway. Furthermore, the lone-pair contribution may be quite large, since the energy denominator is small for nonbonding

Figure 8 Ranges of $^1J(^{15}\text{N}, ^{15}\text{N})$ values

electrons. The most important energy term is that of the lowest singlet–triplet excitation, unpairing the electrons.

The changes in sign of $^1J(^{15}\text{N}, \text{C})$ in Figure 8 can be understood in these terms. Thus, $^1J(^{15}\text{N}, \text{C})$, which is commonly negative, becomes less negative and may become positive when the nitrogen carries a lone pair as in pyridine or *cis*-diazenes $\text{R}-\text{N}=\text{N}-\text{R}$. The value of $^1J(^{15}\text{N}, \text{C})$ becomes negative again if the nitrogen is protonated.

Values of $J(^{15}\text{N}, ^{15}\text{N})$ may vary in a complex fashion if there is a lone pair on each of the nuclei. The coupling constant is very sensitive to the dihedral angle ϕ between the lone-pair orbitals, since they interact to give bonding and antibonding (HOMO) combinations. Calculations on hydrazine, N_2H_4 , in which ϕ is near 90° show that $^1J(^{15}\text{N}, ^{15}\text{N})$ is negative and quite large for an N_2H_4 molecule with $\phi \approx 0^\circ$, falling to zero for the geometry with $\phi = 115^\circ$ and increasing to a large positive value for $\phi \approx 180^\circ$.²⁰⁷ Similarly, for planar systems such as diazenes as in azo compounds ($\text{RN}=\text{NR}$) or diazenido complexes ($\text{M}-\text{N}=\text{NR}$), $^1J(\text{N}, \text{N})$ values are large and negative for *cis* compounds with $\phi \sim 0^\circ$, but large and positive for *trans* compounds, with $\phi \approx 180^\circ$. In longer range couplings, ‘through-space’ orbital overlap provides an additional route for the transmission of coupling information.

The contributions to the spin–spin coupling that are mediated by p,d,... electrons are normally smaller than the contact contribution J^{fc} , and are very small for hydrogen, but may be sizeable if π bonding is present. The orbital term $J^{\text{o}}(\text{A}, \text{B})$ arising from the magnetic effect on nucleus B

of the orbital motion of an electron on nucleus A, and the spin–dipolar term $J^{\text{sd}}(\text{A}, \text{B})$ arising from direct interaction of the spin of an electron on nucleus A with the spin (magnetic dipole) of nucleus B, increase in magnitude with the bond order. In the dinitrogen molecule $\text{N}\equiv\text{N}$ with $^1J(^{15}\text{N}, ^{15}\text{N}) = 2.5 \text{ Hz}$,⁴⁵ a theoretical study²⁰⁸ found that the contact term made the smallest contribution, 0.82 Hz, compared with a dipolar contribution of -1.57 Hz and an orbital contribution of 3.35 Hz. Orbital and spin–dipolar contributions are large in the triply bonded molecules HCN, nitriles, and isonitriles.

The noncontact contributions, also, increase in magnitude when there are electronegative substituents on the coupled nuclei, because of a dependence on the radial term $\langle r^{-3} \rangle_{2p}$. Contact and noncontact contributions are all large in the benzonitrile N-oxide 2,4,6- $\text{C}_6\text{Me}_3\text{H}_2\text{CNO}$, giving an unusual overall value $^1J(^{15}\text{N}, ^{13}\text{C}) = (-)77 \text{ Hz}$.²⁰⁴

6.2 Couplings to Other Nuclei

Nitrogen couplings to other nuclei are normally dominated by the contact interaction. They are sensitive to s character in the relevant bonding orbitals and to the presence of lone-pair electrons. Discussion of the signs is most usefully in terms of the reduced coupling constant K since $\gamma(^{15}\text{N})$ is negative: thus, nitrogen couplings to fluorine are commonly measured in ^{14}N resonance as they are relatively large and the fluoro systems usually have low viscosity.

The periodic trends can be rationalized in terms of stabilization of bonding σ MOs and destabilization of nonbonding (lone pair) MOs with an increase in atomic number down the group or across the row of the Periodic Table. Amine–borane or aminoborane couplings 1K are positive (and relatively small). Values of $^1K(\text{C},\text{N})$ and $^1K(\text{Si},\text{N})$ are normally positive, but $^1K(\text{Sn},\text{N})$ values may be of either sign and $^1K(\text{Pb},\text{N})$ values are negative. Couplings to transition metals are normally positive.

Couplings of the type $^1K(\text{P},\text{N})$ involving P(III) are negative as for $^1K(\text{N},\text{N})$, while couplings to P(V) may be of either sign. Couplings of the type $^2K(\text{P},\text{N})$ are usually small, but may be quite large for *trans* interactions in metal complexes.

Values of $^1K(^{19}\text{F},\text{N})$ are expected to be negative because of the lone-pair contribution. The largest value is $^1J(^{19}\text{F},^{14}\text{N}) = 339\text{ Hz}$ in $\text{FN}\equiv\text{NF}^+$, corresponding to the maximal $^1J(^{15}\text{N},\text{H}) = 135\text{ Hz}$ in the nitrilium ion $\text{HC}\equiv\text{CNH}^+$. The value of $^1J(^{19}\text{F},^{14}\text{N})$ is 231 Hz in NF_4^+ compared with 158 Hz in NF_3 , another lone-pair effect.²⁸

Ligating nitrogen is relatively low in the empirical series of *trans* influence, though above halides or alkoxy ligands. The *trans* influence measures the tendency of a ligand by forming a strong bond to the metal to weaken the *trans* bond in a metal complex, so reducing the magnitude of coupling constants involving the *trans* bond.

6.3 Couplings as Criteria of Structure

Nitrogen couplings may be diagnostic of *cis-trans* or *syn-anti* stereochemistry, conformation, hydrogen bonding, and related medium effects. The couplings are enhanced by protonation, alkylation, or coordination of the nitrogen, and so may be diagnostic of chelation or proton migration. The largest magnitudes of couplings are observed in linear systems. In ligands which may be bent or linear in their attachment to a metal, such as nitroso ($-\text{N}=\text{O}$), diazenido ($-\text{N}=\text{N}-\text{R}$), or hydrazido(2-) ($=\text{N}-\text{NR}_2$) ligands, $\text{M}-\text{N}_\alpha$ coupling constants are reduced on bending; the protonation of the bent α -nitrogen in $[\text{PtCl}(\text{N}=\text{NPh})(\text{PEt}_3)_2]$ increases the $^1J(^{195}\text{Pt},^{15}\text{N})$ value from 157 to 510 Hz .¹²⁵ Couplings are also enhanced by flattening of a pyramidal group, delocalizing the s-type lone-pair electron density. Thus $^1J(\text{N},\text{H})$ values in the hydrazido(2-) ligand $-\text{N}-\text{NH}_2$ resemble those in amides rather than hydrazines, since the hydrazido(2-) ligand is flat.

Such relationships allow coupling constants to be estimated as required to optimize the experimental parameters. Equations relating 1J values to percentage s character in the bond^{197–199} can be used in this way if exceptional bond types are avoided.

7 SOLID STATE STUDIES^{6,7,13,14}

The fast growth of nitrogen NMR studies in the solid state is documented in the annual reports of work on solid state techniques, macromolecules, natural and synthetic, and shielding tensors (Section 5).⁷ Solid state NMR spectroscopy is increasingly being used in materials technology and for biological materials. Because of the volume of this work, reference can only be selective and directed towards new techniques or reviews.^{209,210}

Molecular biology has seen a great increase in nitrogen NMR.^{168,211,212} Peptide and protein backbones, planes, and side-chains can be studied with improved methods of orienting samples mechanically or magnetically. Ordered systems such as nucleoproteins or membrane–protein complexes²¹³ which are insufficiently soluble or mobile for solution studies, or insufficiently ordered for X-ray diffraction techniques, are becoming accessible to NMR study. Solid state NMR can provide spatial information which is lost by tumbling motions in solution, and can also monitor motions which are frozen or blurred in X-ray crystallographic studies.

For many systems, a combination of physical methods is needed; NMR to probe short-range interactions and X-ray crystallography methods showing long-range order.²¹⁴ Solid state NMR provides a useful link between X-ray crystallographic analysis and NMR solution studies, particularly as conformations may vary from solid to more fluid phases. Nitrogen spectra of biological material may be easier to interpret than carbon or proton spectra because of the relatively small number of nitrogens, characteristic shifts, and sizeable shielding range.

Nitrogen-14 properties measured in the solid state include electric field gradient (efg) tensors, quadrupole couplings, dipolar couplings, and spin diffusion²¹⁵ in studies of molecular structure and reorientation. Orientations of the ^{14}N efg tensors and carbonyl ^{13}C shielding tensors provide structural information in amino acids and peptides.²¹⁶ $\text{N}-\text{H}$ bond lengths have been determined with high accuracy from dipolar interactions of ^{14}N or ^{15}N with ^1H .²¹⁷ Static ^{14}N powder spectra were used to study electric field gradients and reorientation in NH_4NCS .²¹⁸ Information on ^{14}N dipolar and quadrupolar couplings is also obtained by lineshape analysis of resonances of a bonded neighbor, whether ^{13}C ,²¹⁹ ^{29}Si in nitrogen-containing ceramics,²²⁰ ^{195}Pt in $\text{K}_2[\text{Pt}(\text{CN})_4 \cdot 3\text{H}_2\text{O}]$,²²¹ etc.

Advantage can be taken of the high natural abundance of ^{14}N by using the ^{14}N nuclear quadrupole interaction to spread nitrogen spectra over a large range, more than compensating for quadrupolar line broadening. This method was used in ^{14}N and ^{13}C measurements of the CCN geometry and ^{14}N quadrupole coupling tensor in glycine single crystals.⁵⁷ The quadrupole interaction shifts the middle of the three ^{14}N energy levels ($I = 1$) relative to the other two, and produces a doublet splitting which is determined by the angular dependence of the first order quadrupole interaction. The second order quadrupole interaction, arising from the closeness of the Larmor and the quadrupole coupling frequencies, shifts the doublet somewhat and makes the overtone transition partially allowed. Information is thus available from the combination of the ^{14}N quadrupole splittings, second order ^{14}N quadrupole shifts, ^{14}N overtone frequencies, $^{14}\text{N}-^1\text{H}$ and $^{14}\text{N}-^{13}\text{C}$ dipolar splittings, and ^{13}C shielding tensor for determining orientations in a peptide plane in oriented samples. Cross polarization is very effective for ^{14}N spectra in amino acids, peptides, and proteins, because of strong NH coupling in the amido/peptide group. Peptide backbone conformations have been studied in this way by two-dimensional $^1\text{H}/^{14}\text{N}$ spectra and crystalline amino acids by $^{13}\text{C}/^{14}\text{N}$ spectra, with use also of $^1\text{H}/^{13}\text{C}/^{14}\text{N}$ triple resonance.^{58,222}

Most nitrogen work in the solid state is done in ^{15}N resonance, using the techniques developed for ^{13}C of static powder patterns or CP MAS methods with high-power

proton dipolar decoupling. The principal components of the shielding tensors (Section 5) are obtained from powder pattern lineshapes, or from the intensities of spinning side-bands at slower spinning rates. The orientation of the principal axis system in the molecular frame is found by the use of oriented specimens or by the observation of dipolar interactions.^{145,147}

Some solid state work has been done in natural abundance of ^{15}N , for example polymer studies of the α -helix and β -sheet components of homopolypeptides²²³ and Nylons,²²⁴ and of polyimines and the conducting polymers which they yield on oxidation.²²⁵ Adsorption studies may be possible in natural abundance of ^{15}N , the occlusion of NPr_4^+ cations in zeolites²²⁶ for example. Enrichment is usually necessary, however, and bioenrichment is particularly useful.

In a historic determination in 1972, the principal elements were reported for the nitrogen shielding tensor in the nitrate ion in ammonium nitrate, distorted by hydrogen bonding.²²⁷ Recently, the principal values of the nitrate shielding tensors in five solid phases of NH_4NO_3 , the phase transitions, crystal packing deformations, motional averaging at higher temperatures, and magnetic nonequivalence at low temperatures, have been examined by MAS and static NMR.²²⁸ Section 5 discusses shielding tensors reported for nitrogen in ammonia and amines, linear groups (iminophosphonium $\text{RN}\equiv\text{P}^+$, nitrile, isonitrile, N_2O , thiocyanate, N_2 , the dinitrogen ligand, $\text{P}\equiv\text{N}$, linear NO), planar groups (amide, peptide, heterocycle, aldimine, ketimine, oxime, nitroso dimer, nitrobenzene, nitrates, nitrite ion, nitroso compounds, azo or diazene, nitrogen oxides), and metal nitrosyls, linear and bent.

The nitrogen tensor has been used as a criterion of bending of the nitrosyl ligand (Section 5),¹⁸³ and to investigate nitrosyl swinging in solid $[\text{Co}(\text{NO})(\text{TPP})]$,¹⁸⁴ and the bent-linear fluxionality of the five-coordinate complex $[\text{RuCl}(\text{NO})_2(\text{PPh}_3)_2]\text{BF}_4$ in solution.²⁴

Catalytic processes are usefully investigated by ^{15}N CP MAS NMR. Acid sites of the Brønsted or of Lewis type may be distinguished by nitrogen compounds of differing basicity, as in studies of γ -alumina and mordenites by the sorption of pyridine or ammonia,^{229,230} and of zeolites by the sorption of ammonia²³¹ or trimethylamine,²³² cf. the interaction of pyridine with coals.²³³ Some adsorption work can be done by conventional NMR techniques, as in the study of acetonitrile on zeolites.²³⁴

Double cross polarization in doubly labeled ^{13}C – ^{15}N bonds, usually from ^1H to ^{13}C to ^{15}N , was developed to follow the progress of these bonds in vivo, in peptide and other linkages, an early application being to protein turnover in soybean leaves.²³⁵

The transferred echo double resonance (TEDOR) technique has been used to select a ^{13}C label by its dipolar coupling to ^{15}N , giving internuclear distances and geometries, in conjunction with the rotational echo double resonance (REDOR) technique measuring a dipolar coupling of the ^{13}C .²³⁶

Biological NMR studies using solid state techniques are discussed further in Section 9.

8 DYNAMICS^{2–7,237,238}

Dynamic processes with a range of timescales have been monitored by nitrogen NMR. Fast motions such as the switching of the ammonium ion in the $^{14}\text{NH}_4\text{Cl}$ lattice are

monitored by relaxation times (Section 3.1). Measurements of T_1 and NOE of the dipolar relaxation of ^{15}N by neighboring protons have been used to probe a variety of molecular motions, from segmental motions of large molecules to migrations of protons between nitrogens (Section 2). HH migrations between the nearby nitrogens, as in porphyrin or phthalocyanine molecules, were mentioned in Section 2.1, and a range of comparable systems has now been studied,²³⁹ most recently, double, triple, and quadruple proton transfers in pyrazoles.²⁴⁰

Hindered motions about N–X bonds are studied by lineshape analysis, 2D spectroscopy, multicoalescence experiments, saturation transfer, or equilibration methods, or by methods involving longitudinal or transverse relaxation times. A large number of isomerization processes involving N–X bonds have been reviewed as to methods of investigation, dynamics, thermodynamics, and theoretical interpretation in terms of quantum mechanical treatments or empirical correlations.²⁴¹

Examples of dynamic studies are fewer in inorganic chemistry. $^{14,15}\text{N}$ NMR spectroscopy has demonstrated kicking motions, as in the bent-linear fluxionality of the imido ligand $\text{M}=\text{NH}$ in concert with a second imido or an alkoxy ligand in solution.¹³⁹ A corresponding fluxionality of nitrosyls in solution was observed for the five-coordinate complex $[\text{RuCl}(\text{NO})_2(\text{PPh}_3)_2]^+$,²⁴ the averaged shift, the temperature dependence, and the equilibrium isotope effect with semienrichment suggesting that the trigonal bipyramidal form with two linear nitrosyls is present in dynamic equilibrium with the square-pyramidal form with one bent and one linear nitrosyl.²⁴ Swinging and spinning of the bent apical nitrosyl in solid $[\text{Co}(\text{NO})(\text{TPP})]$ was detected through changes in the nitrogen shielding tensor¹⁸⁴ (Section 5.5).

CIDNP enhancing absorption or emission in the NMR experiment, has been used in ^{15}N resonance to study a number of reactions in which radical pairs may be involved. The method is highly sensitive and species that give large signals may not be major intermediates. The contribution of radical pair mechanisms to the nitration of arenes by nitric and sulfuric acid mixtures is now thought to be small.²⁴² ^{15}N CIDNP has also been applied to the study of migrations of nitro groups,²⁴³ azo coupling,²⁴⁴ and the loss of dinitrogen from arene-diazonium salts.²⁴⁵ Stable nitroxide radicals, also, are accessible to NMR spectroscopic study.²⁴⁶

9 BIOMOLECULES^{2–7,9,13}

Biological applications of nitrogen NMR have increased in step with the development of NMR technology and have stimulated this development. Many examples of ^{14}N and ^{15}N NMR properties in biological materials have been given above together with the kinds of information now obtainable. Multidimensional correlation spectroscopy increasingly uses nitrogen as well as ^{13}C and ^1H .^{6,7} Other articles describing the use of nitrogen NMR in biomolecular and biological systems are listed at the end of this section.

Unique information can be obtained from nitrogen NMR on in vivo metabolism and cellular dynamics, as well as on protein (polypeptide) backbones, functional groups in enzymes, and DNA and RNA bases. Nitrogen-14 resonance may be used for material in which there is sufficient mobility for motional

averaging^{247,248} and with solid state techniques making use of the quadrupolar interaction (Section 7). Bioenrichment of ^{15}N allows this to be used as a biological tracer in the absence of a stable radioisotope of nitrogen (^{13}N , the most stable, has a halflife of only 10 min). Highly selective bioenrichment can be obtained by supplying the organism with a ^{15}N -labeled nutrient, such as an amino acid. For ^{15}N work in the liquid phase, the dependence of the relaxation time $T_{1\rho}$ and the NOE on the molecular size has been discussed (Section 2.1).

Techniques and applications to biological systems have been described in a number of reviews²⁴⁹ dealing with nucleic acids and nucleotides, enzyme systems, and intact cells,²⁵⁰ amino sugars,²⁵¹ intermolecular interactions,²⁵² solid state peptide studies,¹⁶⁸ and work of pharmacological interest.^{253,254} Nitrogen-15 spectra can resolve differences between diastereotopomers, as of 8-benzyl-5,6,7,8-tetrahydroquinoline in solutions of optically active carboxylic acids.²⁵⁵

In living cells, molecules that are sufficiently mobile can be studied by solution state techniques and bioenrichment of ^{15}N has been used to advantage. The first in vivo study was of a fungus *Ustilago sphaerogena* grow with ^{15}N -ammonium acetate as a nitrogen source, the resonances of small peptides being observed.²⁵⁶ The mobilities of components of bacterial cell walls were estimated quite early on from ^{15}N NOE values, the observable resonances being those of mobile cross-linking groups.²⁵⁷ The biosynthesis of amino acids from ^{15}N -ammonium salts and their intracellular environment was followed in the fungus *Neurospora crassa*²⁵⁸ and in *Brevibacterium lactofermentum*.²⁵⁹

Nitrogen NMR is being used increasingly in metabolic studies using solid state techniques. In DNA from *E. coli* grown with $^{15}\text{NH}_4\text{Cl}$ as the source of nitrogen, 13 of the 14 nitrogens in the bases were distinguished by their dipolar coupling to protons.²⁶⁰ This allowed the NH bond lengths to be measured, complementing the information available from X-ray and neutron diffraction.²⁶¹ DNA and protein spectra were obtained from the filamentous bacteriophage fd infecting the *E. coli*, and 2D spectra from oriented molecules of the virus.²⁶²

Solid state techniques have been developed for the study of nitrogen metabolism in growing plants using double cross polarization (DCP MAS) NMR (Section 8). This required double enrichment in vivo with $^{15}\text{NH}_4^{15}\text{NO}_3$ and pulsed $^{13}\text{CO}_2$ labeling, to form ^{13}C - ^{15}N bonds, examined in intact or lyophilized material. Such DCP MAS NMR has been used to follow the metabolism of methionine²⁶³ in soybean cotyledons, and also of allantoin²⁶⁴ and alanine²⁶⁵ in *Aerococcus viridans*.

Double labeling can establish biosynthetic pathways, such as cyclization to form the N-C(5) bond in isopenicillin N observed as a $^1J(^{15}\text{N},^{13}\text{C})$ coupling.²⁶⁶

With a variety of techniques, therefore, in vivo observation of components of appropriate mobility is now replacing the use of lyophilized (freeze-dried) tissue. Indeed, ^{15}N -labeled glycine has been detected by a probe implanted between the liver lobes, fixed to the abdominal wall, of a live rat.²⁶⁷

1 INTRODUCTION

During the past two decades solid state NMR spectroscopy and its applications have grown rapidly among the chemistry and biochemistry community. The availability of increasingly sophisticated instrumentation and software has created opportunities for conducting experiments in areas that have not previously been available to the general chemical community. These new opportunities have been especially helpful in the study of solids. While the majority of such solid state applications have utilized ^{13}C nuclei, a much broader range of interesting nuclei (e.g., ^{11}B , ^{14}N , ^{15}N , ^{17}O , ^{19}F , ^{23}Na , ^{27}Al , ^{29}Si , ^{31}P , ^{113}Cd , ^{209}Pb , etc.) has emerged for use by solid state scientists and engineers.

Interest in magnetic resonance studies of nitrogen has increased significantly in the past decade. The distribution of nitrogen containing substances in materials important to the chemical, biological, medical, agricultural, and environmental sciences is well documented. The ^{14}N nucleus (99.6% natural abundance, nuclear spin 1) is quadrupolar giving rise to a broad signal while the ^{15}N nucleus has spin 1/2. The relative sensitivity of both nuclei is approximately 1×10^{-3} compared to ^1H . Nitrogen NMR data have been extensively reviewed by Witanowski et al.¹ and by Mason.² Most of the literature describes liquid state isotropic shifts and their relationship to structure elucidation, the importance of solvent effects, and tautomeric equilibria. The combination of a large isotropic shift range, approximately 1350 ppm,¹ and sensitivity to electronic interactions involving the lone pair of electrons make ^{15}N shifts a very sensitive probe of both structural changes and intermolecular interaction.³ These attractive features of the ^{15}N nucleus are off-set by the sensitivity challenges arising from a low natural abundance (0.365%), long relaxation times, small magnetogyric ratio, and a subsequent receptivity factor 2.19×10^{-2} relative to ^{13}C for an equivalent number of nuclei. Hence, much of the data reported has been obtained from ^{15}N

labeled materials although modern high field spectrometers have proven their value in studies at the natural abundance level. A significant amount of attention has recently been focused on the role of nitrogen in biological structures⁴ because of its sensitivity to both hydrogen bonding and intermolecular and long-range interactions. In this document the discussion will be restricted to the ^{15}N nucleus.

2 CHEMICAL SHIELDING

The well known relationship between magnetic field strength B_0 (arbitrary orientation in the z direction), the magnetogyric ratio γ_I of nuclear spin I , and the NMR Larmor frequency ν_0 (in frequency units, Hz) is given in equation (1)

$$\nu_0 = \frac{\gamma_I B_0}{2\pi} \quad (1)$$

where ν_0 is the difference in energy between any two of the allowed states. The magnetic inductive effect at the nucleus is equal to the vector sum of the static magnetic field and an induced magnetization vector arising from electronic currents that exist in the sample. The induced magnetization is proportional to B_0 and the proportionality constant is the sum of the chemical shielding and the magnetic susceptibility of the material surrounding the nucleus of interest. In solids, where rapid motional averaging is absent, all intramolecular currents within the molecule of interest are assigned to chemical shielding. Electronic currents arising from neighboring molecules are assigned to magnetic susceptibility. A more detailed and very useful outline of these interactions is provided by Grant.⁵

The electronic circulation set up by the magnetic induction of the applied field perturbs the effects of B_0 at the nucleus of interest. These electronic currents induce a shielding field, B_s , which may be either paramagnetic or diamagnetic (deshielding or shielding) and this induced field must be added to B_0 in order to obtain the effective field, B_{eff} , experienced by the nucleus of interest (equation (2)).

$$B_{\text{eff}} = B_s + B_0 \quad (2)$$

This effect is portrayed in vector form in Figure 1.

The shielding of the nuclear spin is a tensor quantity, described below, that depends on the electronic environment as well as the molecular orientation in the magnetic field. In solids the molecular orientation is locked into a powder pattern in which the nuclear resonance frequency is a function of the orientation of the microcrystalline particles. The random orientation of these particles leads to broad resonance patterns for each unique nuclear spin. The rich informational content of these powder patterns provides more information about electronic structure than the isotropic shifts observed in rapidly tumbling liquid molecules. Unfortunately, the diversity of the banding arising from multiple unique chemical environments in these broad powder patterns obscures the information content that is available in the isotropic chemical shift. However, the components of the shift tensor in the solid state reveal even more information regarding the subtle differences in electronic and geometrical structural characteristics and

Figure 1 Relationship between the applied field, B_0 , and the shielding field and effective fields (not drawn to scale) B_s and B_{eff}

the various experimental techniques employed to extract this information from solid samples is summarized in Section 3.

The shielding interaction with a nucleus is different for each unique chemical environment or symmetry position relative to the remainder of the lattice structure. Furthermore, the orientation dependence of the magnetic field to the screening currents induced around the nucleus presents an anisotropic environment that can be described by the chemical shift tensor. In principal, a different resonance frequency will be observed for each orientation of the nuclear spin with respect to the external magnetic field and the difference in this screening effect from that of a reference material is defined as the chemical shift. The reference that has emerged in the field is

$$\delta = \begin{bmatrix} \delta_{xx} & \delta_{xy} & \delta_{xz} \\ \delta_{yx} & \delta_{yy} & \delta_{yz} \\ \delta_{zx} & \delta_{zx} & \delta_{zz} \end{bmatrix} \quad (3)$$

external nitromethane ($\delta = 0$) with the convention of negative values for more shielded resonance positions. The chemical shift tensor δ in a general reference frame may be represented by a 3×3 Cartesian matrix that is called a second rank tensor (equation (3)) which can be decomposed into three individual tensors of rank zero, one, and two which are defined as the scalar isotropic chemical shift, the symmetric, and antisymmetric chemical shifts denoted (equation (4)) as

$$\delta = \delta_o + \delta_{\text{sym}} + \delta_{\text{anti}} \quad (4)$$

The isotropic shift, δ_o , of zeroeth rank, is the trace of the Cartesian tensor, e.g., $1/3(\delta_{xx} + \delta_{yy} + \delta_{zz})$, and is invariant to any rotational transformation of the coordinate frame. Hence, δ_o is the only part of the chemical shift tensor that can be measured in solution samples; this the result of rapid tumbling motion of the molecules. The antisymmetric (first rank) and symmetric (second rank,) chemical shifts are given in equations (5) and (6), respectively.

$$\delta_{ij}^{(a)} = \frac{1}{2}(\delta_{ij} - \delta_{ji}) \quad (5)$$

$$\delta_{ij}^{(s)} = \frac{1}{2}(\delta_{ij} + \delta_{ji}) \quad (6)$$

The absence of diagonal elements in the first rank tensor renders these second order infinitesimal shift frequencies immeasurable. The traceless second-rank symmetric matrix contains diagonal elements that can provide first-order anisotropic shifts that add to or subtract from the Zeeman frequencies and are measurable in the NMR spectrum of solids. In the symmetric matrix any change in orientation of the magnetic field in the molecular frame will still leave anisotropic shifts along the diagonal of the transformed second-rank matrix. Unlike the antisymmetric components, the off-diagonal shifts in the symmetric portion of the chemical shift tensor will affect the principal values under the transformations associated with matrix diagonalization.

There always exists some frame in which the matrix in equation (3) is diagonal, in which case the three diagonal elements of the chemical shift tensor are designated as the principal values, δ_{11} , δ_{22} , and δ_{33} . By convention the order of the principal values are given as $\delta_{11} \geq \delta_{22} \geq \delta_{33}$, with δ_{11} representing the highest frequency (least shielded) component. The axis system in which the symmetric chemical shift matrix is diagonal is designated the principal axis system (PAS). The diagonal components are the principle values in the PAS while the remaining three (off-diagonal) terms are the Euler angles which define the directions of these principal values in the molecular frame. Hence, the complete description of the chemical shift tensor requires six elements of the shift tensor. The breakpoints in a powder pattern provide the principal values of the chemical shift tensor. The off-diagonal terms can only be obtained experimentally by tracking the chemical shift of each unique nucleus as a molecule (e.g., a molecule in a single crystal) is rotated in the magnetic field. These data can then be transformed into any of a number of reference frames that can be used to determine the orientation of the tensor in the molecular frame. The details of these experiments and transformations are described in a general outline by Orendt⁶ and in detail by Grant⁵ and Sherwood.⁷

The difficulties associated with growing single crystals and then acquiring the necessary orientational data is daunting, time consuming, and complicated by the reality that acquiring a single crystal of sufficient size for NMR experiments is usually not practical. However, sufficient single crystal data, together with theoretical simulations of the shift tensors, have been acquired to demonstrate that quite good approximations can be obtained for the orientation of the shift tensor principal axis system on the molecular frame.^{8,9} Hence, the various types of experiments that provide only the principal values of the shift tensor on powder samples^{6,10} are sufficient, when combined with appropriate theoretical calculations, to describe the off-diagonal elements which fix the orientation in the molecular frame with reasonable accuracy (see Section 4.3). To date, the majority of chemical shift tensor data appearing in the literature has been restricted to the ^{13}C nucleus and the latest, but somewhat dated, compilation of these data together with available data on ^{15}N shift tensor principal values has been provided by Duncan.¹¹ The acquisition of shift tensor data on solid materials, however, has expanded considerably in the past 10–15 years as line narrowing methods and techniques have become available. A review has described these experimental advances⁶ but additional major advances in multidimensional experiments have recently appeared^{12–14} and are described in another article in this encyclopedia,

Magic-angle Turning Spectra of Solids Involving 5π -pulse Sequences.

Despite the challenges faced with obtaining shift tensor data, new experimental techniques now enable investigators to obtain high quality ^{13}C shift tensor data on molecules containing more than sixty unique carbon atoms¹⁰ and ^{15}N shift tensors at the natural abundance level on molecules containing as many as five nitrogens (guanine)¹⁵ and eight non-equivalent nitrogens in potassium penicillin V.¹³

3 EXPERIMENTAL TECHNIQUES

^{15}N chemical shift tensor data have been reported using five different types of experimental techniques: (1) single crystal studies; (2) analysis of static powder patterns and off-magic-angle spinning on simple ^{15}N enriched heterocycles; (3) analysis of powder patterns utilizing the dipolar interaction between ^1H - ^{15}N or adjacent ^{13}C - ^{15}N labeled pairs; (4) powder patterns obtained by means of dynamic nuclear polarization experiments; (5) two-dimensional experiments such as polarization inversion spin exchange at the magic angle (PISEMA), and the five- π pulse experiment five pi replicated magic angle turning (FIREMAT).

3.1 Single Crystals

A single crystal study of L-hystidine-HCl-H₂O¹⁶ reported the full tensor of the two imidazole nitrogens in the amino acid while a single crystal study of $[1-^{13}\text{C}]\text{glycyl}[^{15}\text{N}]\text{glycine}$ provided the principal values of the ^{15}N tensor and its orientation in the molecular frame.¹⁷

3.2 Static Powders and Off-Magic Angle Spinning

The major portion of the ^{15}N shift tensor data has been obtained by static powder pattern analysis. Illustrative examples of static experiments on ^{15}N -enriched materials include: studies of the various phases of NH_4NO_3 ,¹⁸ protonated and non-protonated species in simple five- and six-member nitrogen heterocycles,¹⁹ porphyrin complexes,²⁰ cation binding in a membrane-bound polypeptide,²¹ substituted benzonitriles,²² off-angle fast sample spinning of an isolated ^{15}N - ^{15}N diazo system,²³ static and off-angle fast sample spinning of substituted pyrazoles,²⁴ secondary structure of peptides containing L-alanine²⁵ and poly(β -benzyl L-aspartate),²⁶ substituted benzonitriles,²⁷ the amide fragment of acetanilide and *N*-methylacetanilide,²⁸ and the relationship of the δ_{33} principal value to the hydrogen bond length in the glycine residue of some oligopeptides.²⁹

3.3 Dipolar Interactions in Powders

^{15}N shift tensor principal values and their orientation in the molecular frame have been determined through the dipolar interaction between proton and nitrogen dipolar coupling in peptides,³⁰ tryptophan and histidine side chains,³¹ the phenylalanine residue,³² the dipolar tensors for the peptide bond in $[1-^{13}\text{C}]\text{glycyl}[^{15}\text{N}]\text{glycine-HCl-H}_2\text{O}$,³³ peptides of the form *N*-acetyl $[1-^{13}\text{C}]\text{glycyl}[^{15}\text{N}]\text{-X-amide}$ where

X = glycine, alanine, and tyrosine³⁴ and L $[-^{13}\text{C}]\text{alanyl-L-}[^{15}\text{N}]\text{alanine}$,³⁵ an analytical approach for the determination of the principal value σ_{33} of the amide ^{15}N chemical shift tensor element with respect to the molecular frame,³⁶ studies of the nitroso-groups in nitrobenzene and *p*-nitroso-*N,N*-dimethyl aniline (in which a very large CSA anisotropy of 1472 ppm was observed),³⁷ the two-dimensional PISEMA data on $[1-^{15}\text{N}]\text{-2'-deoxyguanosine}$,³⁸ the three-dimensional powder patterns of $^{15}\text{N}_{\epsilon 1}$ -tryptophan and $^{15}\text{N}_{\pi}$ -histidine side chains,³⁹ shift tensor values and orientation in the molecular frame in ^{13}C and ^{15}N labeled uracil.^{40,41}

3.4 Dynamic Nuclear Polarization Experiments on Powders

Hu et al.^{42,43} reported large ^{15}N DNP enhancement factors in benzamide (260, compared to CP data) and greater than 900 in carbazole and were able to compare the principal values of the shift tensors in powdered samples of these two molecules with those obtained by standard cross polarization and single pulse experimental techniques.

3.5 Two-Dimensional Experiments

A variety of two-dimensional experiments designed for separating the isotropic and anisotropic chemical shift information were instrumental in advancing resolution and data analysis of complex molecular systems.⁴⁴⁻⁵⁰ The magic angle turning experiments, first conceived by Gan,⁵¹ paved the way

Figure 2 A two-dimensional natural abundance ^{15}N spectrum is shown in which the isotropic shift spectrum with no spinning side bands is plotted vertically on the left while the isolated spinning sideband patterns for the six resolved peaks are plotted on the right, connected to the corresponding isotropic peaks by guide lines

for development of experimental tools^{12,13} that can reveal an amazing amount of detail regarding CSA in complex molecular systems. Recent modifications to the 5- π pulse experiments, FIREMAT¹³ and 2D-PASS¹⁴ have been particularly exciting in significantly expanding the range and complexity of molecules that can be studied. These two experiments, while related by virtue of a common 5- π pulse sequence for generating the two-D data set, possess important differences that are detailed in Ref.¹⁰ Taking advantage of TIGER data processing in the FIREMAT experiment,⁵² one is able to optimize S/N and resolution in the evolution dimension and obtain high quality ¹³C data on molecules with more than 60 different tensors. The power of the FIREMAT experiment can be seen by examining the ¹⁵N spectrum of penicillin V in Figure 2. Potassium penicillin V has two nitrogen atoms and, at ambient temperature, four molecules per asymmetric unit.¹³ Conformational differences in these molecules split the NH nitrogen into the four peaks shown between -271.7 ppm and -275.3 ppm. The conformational differences do not affect the ring nitrogen to the same extent and three of the resonances are degenerate at -212.5 while the fourth is at -214.0 ppm. The FIREMAT experiment has also been used to obtain ¹⁵N shift tensor data at the natural abundance level on nucleic acid bases,¹⁵ purine,⁵³ and indolazines.⁵⁴

4 RESULTS

4.1 Characteristics of Principal Values in Nitrogen Heterocycles

For convenience in consideration of ¹⁵N shift tensors in organic molecules the discussion will be restricted to nitrogen heterocycles since this general class of compounds is ubiquitous in nature. The relatively simple five- and six-member heterocycles have been shown to provide the framework for understanding the shift tensor data in more complex heterocyclic structures including indolazines, the nucleic acid bases and related compounds. Consideration of ionic species also

Figure 3 Definition of the different types of nitrogen atoms present in five- and six-member nitrogen heterocycles. The terms “n” and “p” represent non-bonded lone pair and protonated or bonded, lone pair, respectively

reflects the effects of hydrogen bonding interactions on the nitrogen shift tensors. This is especially interesting because of the lone pair of electrons. The structures portrayed in Figure 3 provide a useful framework from which to understand the experimental shift tensor data.

It is found that four different types of nitrogen tensors are present in simple nitrogen heterocycles. For convenience, the nitrogens with non-bonded lone electron pairs in five- and six-member rings shall be referred to as **5-n** and **6-n** types (such as pyrrole anion and the non-protonated nitrogens in imidazole and benzimidazole) and protonated **5-p** and **6-p** types (e.g., pyrrole, the protonated sites in imidazole and benzimidazole, the imidazolium cation, and the pyridinium cation).

Figure 4 presents a correlation diagram of the principal values of 12 simple heterocyclic structures. Quantum mechanical calculations were used to assign the orientation of the principal values to the molecular frame and to provide insight into the effects of electronic structure on the chemical shielding. These orientation assignments can be made with reasonable accuracy (estimated error of ± 10 degrees based on work on uracil)⁵⁵ if

Figure 4 Correlation of the ¹⁵N chemical shift principal values in 5- and 6-member heterocycles. The principal values are marked by solid lines, and the symbols indicate their approximate orientation in the molecular frames as described in Figure 5

Figure 5 Orientation of the in-plane principal components in nitrogen heterocycles. δ_r and δ_t are depicted in the figure and lie in the plane of the ring approximately in the tangential and radial directions of the ring. $\delta_\perp$ is perpendicular to the ring. (*J. Am. Chem. Soc.*, published with permission)

sufficient structural data (e.g., crystal structure, bond length,) is available.^{56,57}

A cursory inspection of Figure 4 illustrates the differences in the spans of the principal values of the nitrogen types. That the span of pyridine (622 ppm) is not unique as demonstrated by the span of 4-nitropyridine (674 ppm). In pyridine one observes that the δ_{11} shift component is oriented tangential to the ring, a direction that is also perpendicular to the lone pair (see Figure 6). When the hybridization of the nitrogen is changed from the **6-n** to the **6-p** type either by protonation, alkylation, or by *N*-oxide formation the tangential component crosses over the radial component, thus reducing the span of the shift tensor components by approximately 1/2 (to a range of 338–351 ppm). A similar affect is noted for the **5-n/5-p** case. The span in the pyrrole anion (333 ppm) is reduced to 192 ppm in pyrrole. Comparable effects are noted in each molecular pair studied. The data of Hoelger et al.²⁴ exhibit the same phenomena in the amine/imine pair of nitrogens in substituted pyrazoles.

The orientation of the shift tensor on the molecular frame of the compounds containing **5-n** type nitrogens corresponds to that found in pyridine (**6-n**). The span of the **5-n** tensor

Figure 6 Electron orbitals making the largest contributions to the chemical shift principal components in pyridine. R corresponds to the lone pair in pyridine and R=H, O, or CH₃ in pyridine hydrochloride, pyridine-*N*-oxide, and *N*-methylpyridine. (*J. Am. Chem. Soc.*, published with permission)

components is 337–374 ppm, a range that is nearly identical to that of the **6-p** nitrogens. In a manner similar to that noted for pyridine, protonation of the **5-n** lone pair inverts the order of the radial and tangential components and also significantly reduces (again, by approximately 1/2) the span of the **5-p** type nitrogens (to a range of 172–206 ppm). This reduction of span for the **5-n** and **5-p** species, compared to the respective **6-n** and **6-p** species, may be attributed to the larger degree of localization of the six π -electrons in five-member heterocycles compared with the six-member rings.⁵⁸ The increase of the localization of the π -electrons increases the electronic repulsion energy, thereby increasing the energy gaps corresponding to the $\sigma-\pi^*$ and $\pi-\sigma^*$ orbitals which dominate the paramagnetic contribution to the in-plane components. Thus, the paramagnetic contribution to the in-plane components of the shielding term decreases which reduces the shift tensor span.

The effects of interaction of the lone pair with neighboring atoms, whether bonded or non-bonded, is a matter of extreme interest and will be described in Section 4.3.

4.2 The Nucleic Acid Bases

The simple nitrogen heterocycles can be used as a guide to understanding the electronic structure and intermolecular interactions in the nucleic acid bases. Employing a combination of two-dimensional experimental techniques (PHORMAT, TIGER data processing, and FIRMAT) that were dependent on the complexities of the ¹⁵N spectra, the shift tensors were

Figure 7 Correlation diagram of the ¹⁵N shift tensor principal values in nucleic acid bases. Dashed lines are isotropic shift values

obtained on isotopically enriched adenine, and at natural abundance on thiamine, guanine, and cytosine.¹⁵ The principal values obtained, together with data previously reported on uracil,⁴⁰ are presented as a bar graph in Figure 7 in order to visualize the relationship between the various shift tensor patterns.

The ¹³C and ¹⁵N shift tensor data obtained on purine⁵³ provides a useful model for interpreting the patterns observed in the nucleic acid bases. The purine data were obtained under separate sets of conditions and the position of the tautomeric proton could be definitely identified (by means of the ¹³C isotropic shift data) as residing at either the N-7 or the N-9 position. The interpretation of the data is further confirmed by comparing the purine ¹⁵N data with that of the simple nitrogen heterocycles previously described. In the five- and six-member heterocycles (Figure 4) the span ($\delta_{11} - \delta_{33}$) of the shift tensors of the **5/6-p** nitrogens are of the order of 1/2 that of the **5/6-n** nitrogens (compare, for example, the spans of N-1 and N-3 in benzimidazole in Figure 4). The N-7 and N-9 tautomeric structures in purine mirror this effect and, by comparing the spans of the N-7/9 positions in adenine and guanine (Figure 8), the position of the tautomeric proton is clearly evident in these two compounds. Furthermore, the spans of the N-1 and N-3 tensors in uracil and thiamine clearly indicate that the two labile protons occupy these sites while the cytosine data suggest that N-1 is the preferred site, in accordance with x-ray data. In the case of guanine the shift tensor data is consistent with the proton occupying the N-1 site.

Figure 8 Comparison of shift tensor principal values in purine ring structures. The purine data is taken from Ref.⁹ while the adenine and guanine data were taken from Ref.¹⁵

4.3 Effects of Hydrogen Bonding

The large changes in the shift tensor principal values provide a means for assessing hydrogen bonding in a wide range of heterocyclic ring systems. Using density functional theory (DFT) Facelli³ simulated the shift tensor data in benzamide and these results, together with simulations of uracil,⁴⁰ highlighted the importance of including hydrogen bonding, and in general, intermolecular interactions in the calculation of ¹⁵N chemical shift tensors. Further evidence for the importance of these intermolecular interactions in the calculation of ¹⁵N chemical shift tensors can be found by analysis of these tensors in the series of heterocycles portrayed in Figure 4.

For these compounds the rms error between experimental and DFT calculated values, which did not include intermolecular effects, was approximately 30–40 ppm. This large scatter is approximately an order of magnitude greater than that found in simulated data on polyaromatic hydrocarbons.^{56,57}

Utilizing the imidazole structural information obtained from neutron diffraction data it is possible to improve the chemical shift calculations and to examine the effects of hydrogen bonding on the ¹⁵N shift principal values using a dimer model.¹⁹ The correlation between experimental and calculated shift principal values in imidazole, with and without intermolecular interactions, is shown in Figure 9. The rms error of the predicted shift principal values is 40.9 ppm using an optimized geometry and is 13.8 ppm when the structural data includes the position of the hydrogens in the lattice structure along with the effects of hydrogen bonding.¹⁹ Using the neutron diffraction data without including the intermolecular hydrogen bonding

Figure 9 Experimental versus predicted chemical shift values for imidazole. The DFT method was used to calculate the ¹⁵N shift tensor values using the neutron diffraction structure and including the effects of intermolecular interactions due to hydrogen bonding. The letters r, t, and p refer to the radial, tangential, and perpendicular components of the shift tensors. The legends N/HB and NH/HB designate predictions based on intermolecular interactions due to hydrogen bonding for the **5-n** and **5-p** nitrogens, respectively. (*J. Am. Chem. Soc.*, with permission)

effects produces only a modest improvement in the calculated values over those obtained with the optimized geometry. Introduction of intermolecular effects in the simulation of the nucleic acid bases plays a significant role in improving the correlation of experimental and theoretical result, reducing the rms error by a factor of two.¹⁵ Given the 3–4 fold greater span of the nitrogen shift tensor, a rms error of 14 ppm in imidazole and 16 ppm for the nucleic acid bases compares favorably with the 3–5 ppm rms errors obtained in simulations of ¹³C chemical shift tensors in polycyclic aromatic hydrocarbons based on x-ray structure data.^{56,57}

5 CONCLUSIONS

¹⁵N chemical shift tensors in heterocyclic compounds are very sensitive to the hybridization of the nitrogen atom and changes in the tangential component can vary from 200 ppm to as much as 340 ppm in five- and six-member rings, respectively, when the nitrogen lone-pair hybridization is changed. The changes in the magnitude of the in-plane components are so large that these effects may be useful in probing intermolecular interactions associated with hydrogen bonding in biological systems. It is possible to measure and spacially assign the principal components of the ¹⁵N chemical shift tensors obtained from powder samples in heterocyclic compounds. The assignments of the chemical shift tensor components are critical for analyzing the relationship between the electronic structure and shift tensors. In all the compounds studied, the most deshielded component, δ_{11} , is in the plane of the ring and approximately perpendicular to the plane containing the bonding-antibonding or HOMO-LUMO pair of orbitals with the smallest energy gap. The most shielded component, δ_{33} , is always perpendicular to the plane of the ring, as in the ¹³C tensors of aromatic compounds and is less sensitive to changes in the hybridization of the nitrogen atom than the principal components in the plane of the ring.

Employing modern instrumentation and experimental techniques that have been optimized for obtaining shift tensor data, it is now possible to study nucleic acid materials at the natural abundance level or with isotropic enrichment depending on the relaxation times and spectral complexity. The nucleic acid bases exhibit the same sensitivity to small changes in molecular geometry and environment noted for the five- and six-member heterocycles. Even for nitrogens with similar hybridization, differences as large as 50 ppm are found in corresponding principal shift components. Theoretical techniques now available enable the investigator to simulate the molecular environment with reasonable confidence. The agreement between experiment and theory is highly dependent on the molecular model used in the calculations, and molecular models that include the intermolecular interactions show superior correlation with the experimental values.

Structures are at the heart of organic chemistry. The brains are in using structures and structural theory to achieve desired chemical transformations. Before the 1920s, the only way to determine the way that the constituent atoms in an organic molecule are bonded together was by degradation and synthesis. For complex molecules, the process of determining structures was often arduous, particularly when there were few functional groups as with many steroids. Nonetheless, extraordinary progress was made, even if slowly, by a combination of experimental and deductive skills.

After 1920, X-ray diffraction slowly became the definitive procedure for determining structures for substances that can be obtained in crystalline form and are otherwise amenable to diffraction techniques. In its earlier days, X-ray diffraction was decisive in structural studies of steroids, penicillin, vitamin B₁₂ and, later, for many other important substances, often natural products, of which a recent triumph was of nitrogenase. The representations of structures so obtained are of necessity essentially static, although the root-mean-square amplitudes of thermal vibrations of the atoms in the crystal are usually determined.

For liquids or solutions, X-ray diffraction is not helpful, but considerable structural information is obtainable by infrared, Raman, ultraviolet, and mass spectroscopies. However, these alone do not often allow a complex structure to be determined. Applications of nuclear magnetic resonance spectroscopy to organic chemistry in the early 1950s provided an entirely new structural analysis tool that surely must rank as the most important advance in organic chemistry in the last 50 years, if not in the more than 100 years since the development of classical organic structural theory by Kekulé and Loschschmidt. This is a bold statement for which justification will be supplied in what follows. The practical details of running NMR spectra on organic compounds will not be covered here; there many excellent books for this purpose. Instead the focus will be on illustrative features of how NMR is used in organic chemistry.¹

NMR spectra require samples containing atomic nuclei possessing magnetic moments and, fortunately, all of the kinds of atoms of general interest to organic chemists have one or more isotopes that have magnetic moments. Unfortunately, not all of these magnetic nuclei are equally capable of giving useful resonance signals and, furthermore, many have low natural isotopic abundances.

Of the atomic nuclei contained in the majority of organic compounds, an approximate order of importance for NMR

spectroscopy is ¹H, ¹³C, ¹⁵N, ¹⁹F, ³¹P, ²H, ¹⁴N, ¹⁷O, ³H, and ³³S. It should be understood that NMR is not an especially sensitive spectroscopic procedure. For this reason, it is important that the magnetic moment of the nucleus and its natural abundance be reasonably large. It is also important that the linewidths of the nuclear resonances be narrow and this means that the magnetization induced in the nuclei should not decay away (relax) too quickly. An important contributor to the decay of induced nuclear magnetization arises when the nuclei have electric quadrupole moments and such quadrupole moments are associated with nuclei that have nuclear spins (*I*) greater than $\frac{1}{2}$. Consequently, it is advantageous to have the nuclear spin be $\frac{1}{2}$ and this is true for ¹H, ³H, ¹³C, ¹⁵N, ¹⁹F, and ³¹P, but not for ²H, ¹⁴N, ¹⁷O, ³³S, or for chlorine, bromine, and iodine. Except for fluorine, the halogens in organic compounds do not give useful NMR spectra. Hydrogen-3 is a superb nucleus for observation by NMR, with spin- $\frac{1}{2}$ and the largest known magnetic moment of any nucleus. However, it is radioactive with a halflife of ~13 y, which means that to have observable quantities is to have a great deal of radioactivity, even in a small sample.

Proton NMR, besides having the advantage of $I = \frac{1}{2}$, benefits from both a large magnetic moment and high natural abundance, as well as being very common in organic compounds. Carbon NMR can only be achieved with ¹³C which has $I = \frac{1}{2}$ but with a magnetic moment only one-fourth that of ¹H and a natural abundance of 1.1%. These factors make natural abundance carbon NMR more difficult to obtain than proton NMR by a factor of about 6000. Matters are still worse with natural abundance ¹⁵N with a magnetic moment one-tenth of that of protons and an abundance of only 0.37%. These unfavourables translate to an increased difficulty of detection relative to protons by a factor of about 260 000.

Many organic molecules can exist in multiple conformations with different stabilities. X-Ray diffraction of organic crystals normally allows us not only to decide which atoms are bonded to one another, but also shows which conformation(s) exist in the crystals. Because most chemical transformations are carried out in solution, it is often vitally important to be able to determine which conformations exist in solution and it is well known that conformational preferences determined for crystals cannot be reliably extrapolated to the same material in solution. NMR has special importance for its ability to determine, at least qualitatively, conformational equilibria in solution and, in many cases, it is unique in its potential for measuring the rates of establishment of such equilibria. Further attention to this point will be given later.

The observables of NMR that apply with particular emphasis to organic chemistry are chemical shifts, spin-spin couplings, nuclear spin relaxation rates, signal intensities, and lineshapes. Lineshapes are particularly relevant when influenced by chemical kinetics of one kind or the other. For structural analyses, NMR spectroscopy is in many ways closely related to the classical degradation procedures. Degradation is used to break up molecules with the hope of being able to produce recognizable fragments with known bond connectivities. The structure is then deduced by fitting the pieces back together in the manner of a jigsaw puzzle. NMR operates to show the individual pieces of the puzzle while they are in place, and the structural analyst has to deduce the relationships of the pieces to one another to determine the connections between the atoms.

Differences in chemical shift of the resonances for a given kind of magnetic nucleus are the result of differences in the shielding of the nuclei by their electronic environments. Precise predictions of shieldings from first principles of quantum mechanics are difficult, but many useful qualitative generalizations are available. Proton (^1H) chemical shifts are customarily measured in Hz relative to the proton resonance of tetramethylsilane. Because the shifts so measured are strictly proportional to the strength of the magnetic field and NMR spectrometers operate at a variety of field strengths, it is convenient to divide measured shifts in frequency units by the spectrometer frequency and multiply by 10^6 . Shifts are then expressed by ppm, dimensionless quantities, that allow immediate comparisons between measurements made at different field strengths. Spin–spin couplings are independent of field strength and should always be reported in Hz. Nuclear relaxation rates are commonly expressed in characteristic times, T_1 or T_2 , and range over widely different values from μs to hours. The reciprocal of the characteristic time is the usual chemists' rate constant, k , that is most commonly expressed in s^{-1} . Integrals of line intensities, when properly measured, correspond to quite precise relative concentrations of the substances or groups corresponding to the lines integrated.

Some of the wealth of information obtainable by NMR can be illustrated by the very well-studied examples provided by ethanol and its one stable isomer, dimethyl ether. The ^1H spectrum of ethanol, by showing three chemically shifted groups of resonances with intensity ratios of 1:2:3 corresponding to HO, CH_2 , and CH_3 , distinguishes itself in an instant from that of dimethyl ether which displays only a single sharp ^1H resonance line for its two CH_3 groups. The single resonance for dimethyl ether might seem entirely obvious, but is not really so, because we would not expect all possible rotational angles about the C–O bond to be equally favorable. A possible conformation is shown by structure (1).

For a molecule having this structure and symmetry, it will be seen that there should be four hydrogens with the same chemical shift and two others with a different chemical shift. That only one shift can be observed at any magnetic field so far available is a consequence of very rapid rotation about the C–O bonds, whereby the different shifts are averaged to a single value over the lifetimes of the magnetic states of the hydrogen nuclei. Here, a confident judgment can be made that the rate of rotation is fast by simple inspection of the spectra. Infrared and Raman spectra can be used to reach similar conclusions, but not in any very simple way. It is expected that there will be at least some barrier to rotation of the methyl group about the C–O bond and that different proton chemical shifts would be observed at temperatures low enough that the interval between rotations is comparable or longer than the lifetimes of the magnetic states. However, for dimethyl ether, this temperature is lower than can be usefully achieved with

present-day commercial NMR spectrometers. Nonetheless, if a CH_3 group is located in an environment where its rotation is restricted by virtue of severe steric crowding, and where different chemical shifts are predicted for the hydrogens by symmetry considerations, then it is possible to measure the rate of rotation as a function of temperature and determine the activation parameters for rotation. One example is provided by the molecule (2).

Here, steric hindrance is such that the barrier for rotation about the C– CH_3 bond is about 46 kJ mol^{-1} (11 kcal mol^{-1}) as compared to perhaps a 12 kJ mol^{-1} (3 kcal mol^{-1}) rotational barrier for the O– CH_3 bond of dimethyl ether.

Another lesson from dimethyl ether is that nuclei having the same resonance frequency do not show the phenomenon of spin–spin splitting. Viewed in the simplest way, spin–spin splitting arises because the resonance frequency of a given nucleus depends on the magnetic field that the nucleus is experiencing. Now, if another nucleus with a magnetic moment is in the same molecule, then the magnetic field that this second nucleus generates either augments or decreases the magnetic field at the first nucleus, depending on the magnetic quantum state of the second nucleus. In quantum terms, this means that the energy levels of the first nucleus depend on the magnetic quantum state of the second nucleus. Because the magnetic moment of the nucleus does not depend on the magnitude of the applied field it should be clear why the magnitudes of coupling constants are independent of the applied field.

The way of looking at the origin of spin–spin splitting that we have just described is incomplete, because the protons of the methyl groups of dimethyl ether might be expected to cause each other's resonances to be split but, as we have said, they are not split. The fact is that, while the protons of the methyl groups of dimethyl ether do have magnetic energy-level differences that correspond to spin–spin splittings, transitions between these levels are 'forbidden', so no splittings are observed. This behavior is rather general for protons with the same chemical shift.

Spin–spin splittings provide very valuable structural information and if for some reason it is desired to know the values of the J coupling constant between normally equivalent protons, as of the methyl groups of dimethyl ether, this can be achieved by replacing one or two (not three) of the hydrogens by deuterium. Because deuterium has a smaller resonance frequency than hydrogen by a factor of 6.5, the transitions that lead to spin–spin splitting of hydrogen by deuterium are now allowed and, with substitution of one deuterium, a 1:1:1 triplet with a spacing of 1.66 Hz is observed for the resonances of the two remaining and equivalent methyl group protons. The triplet is a consequence of the nuclear spin of deuterium being unity and its having magnetic quantum states of +1, 0, and

—1. The spacings of the triplet correspond to the $^2J(\text{H,H})$ coupling divided by $\gamma_{\text{D}}/\gamma_{\text{H}}$ and need to be corrected if $^2J(\text{H,H})$ is desired. The value of $^2J(\text{H,H})$ so obtained is 10.8 Hz and is not strictly equal to $^2J(\text{H,H})$, because there will be a small isotope effect resulting from the substitution of D for H.

It is very useful to classify the magnetic nuclei in various kinds of molecules with regard to their potential patterns of spin–spin splittings. The protons of CH_4 will be in equivalent magnetic environments (unless the molecular symmetry is reduced by something like being adsorbed on a metal surface) and, furthermore, the $^2J(\text{H,H})$ coupling constants between each of the four protons are expected to be equal. We categorize such a grouping as A_4 . The situation for $\text{CH}_3\text{—CH}_3$ undergoing rapid rotation around its C–C bond is not the same, even though all six protons will have the same chemical shift. The difference here is that there are two different coupling constants, $^2J(\text{H,H})$ for the protons in each methyl group and $^3J(\text{H,H})$ between the methyl groups. The characterization is now $A_3A'_3$. With many of the possible arrangements of spin–spin splitting groups, the chemical shift difference is important to the line positions and intensities. Two coupled, spin- $\frac{1}{2}$, nuclei with the same magnetic moment and a shift difference large compared to the coupling constant J between them will give two doublets with all of the resonances having equal integrated intensities. Also, the spacing between the doublet centers will be equal to the chemical shift difference. If the chemical shift difference is comparable to the coupling then the outer lines of the doublet pair lose intensity while the inner lines get stronger. In addition, the spacing between the doublet centers is now not the shift difference δ , but instead $(\delta^2 + J^2)^{1/2}$. The first case, we designate as AX and the second as AB. Letters close together in the alphabet are used to represent shift differences comparable to couplings, those farther apart in the alphabet are used for large shift differences. The distinction can be blurred by which spectrometer is used. If a shift difference is 0.333 ppm and the coupling is 5 Hz, the separation between the doublet centers when observed with a spectrometer at 30 MHz will be $(100 + 25)^{1/2}$ or 11.18 Hz, a difference of 1.18 Hz (a 12% deviation) from what would be expected for an AX system. But at 600 MHz, the same separation will be $(40\,000 + 25)^{1/2}$ or 200.06 Hz, which is only 0.06 Hz (a deviation of 0.03%). Any ambiguity about whether chemical shifts are large with respect to the couplings is easily resolved when the shift units are in Hz rather than ppm. When there is more than one kind of nucleus in the spin system, the chemical shift difference in effect will be very large and so fluoroethane would be designated by A_3B_2X . This way of classifying spin systems is very widely used and helpful in understanding where spin–spin couplings are expected to be more complex than predicted by simple counting on one's fingers.

The oxygen NMR of dimethyl ether is only possible to observe for ^{17}O because neither ^{16}O nor ^{18}O has a nuclear magnetic moment and unfortunately ^{17}O has a very low natural abundance (0.037%). A further problem arises because the ^{17}O nucleus has a sizable electric quadrupole moment that normally makes the lifetimes of the states very short, thus usually giving broad featureless resonances for which chemical shifts, but seldom coupling constants, can be obtained.

The chemical shift of the naturally occurring ^{13}C in the carbons of dimethyl ether can be easily obtained at the natural abundance level, with, or without, proton decoupling. Without proton decoupling, the ^{13}C resonance will be split into a quartet

by its three directly attached protons. The $^4J(\text{H,H})$ couplings between the methyl hydrogens across the ether oxygen bridge will not correspond to allowed transitions if both carbons are ^{12}C , but if one is ^{13}C and $^4J(\text{H,H})$ is large enough, then there will be a 1:3:3:1 quartet of transitions corresponding to spin–spin splittings, because now the frequencies of the methyl protons on one or the other carbon will be caused to differ by virtue of the $^1J(^{13}\text{C,H})$ coupling. $^4J(\text{H,H})$ couplings of this kind are usually small, 0.3–2 Hz.

To return to ethanol and its proton NMR spectrum. The shifts are in the order of increasing frequency from the usual standard, tetramethylsilane (TMS), the CH_3 , the CH_2 , and the OH protons. The usual rationalization of the sequence of these shifts (for pure liquid ethanol at 1.2, 3.7, and 5.3 ppm, respectively) is on the basis of electronegativity. The oxygen by virtue of its superior electronegativity attracts electrons from the OH hydrogen's valence shell, thus decreasing the diamagnetic shielding of that nucleus and causing its resonance to appear at higher frequency than TMS relative to the CH_2 or CH_3 protons. The shifts of the resonances of the CH_2 and CH_3 protons can be rationalized similarly, because the CH_2 carbon is attached to an oxygen while the CH_3 carbon is connected to another carbon. In general, this sort of reasoning has utility, as shown by the fact that there is a good linear relationship between the difference in proton shifts between the XCH_2 and CH_3 protons for XCH_2CH_3 and the Pauling electronegativities when X is halogen.

Matters are actually not nearly so simply related to electronegativity for the resonance of the OH proton, because its shift is very sensitive to intermolecular hydrogen bonding and, because, when such hydrogen bonding is decreased by dilution with a nonhydrogen bonding solvent like tetrachloromethane, the OH resonance moves toward that of TMS. At high dilution, the OH resonance is actually observed at a *lower* frequency than that of the CH_3 resonance, even though the OH proton is attached to a very electronegative atom. This is not an uncommon finding when hydrogen bonding is important and, in many proteins, strongly hydrogen-bonded protons are found at as much as 12–18 ppm from tetramethylsilane. Clearly, NMR provides a useful technique for the study of hydrogen bonding. Also, it should be remembered that the electronegativity of X in substances with X–H bonds is not necessarily a good predictor of the ^1H shifts in such substances.

Among the factors that influence ^1H shifts, besides electronegativity, is the aromatic ring-current effect. This effect arises because the π electrons in an aromatic ring are caused to circulate coherently through the π -orbital system under the influence of a magnetic field when the field axis is perpendicular to the plane of the ring. The effect is diamagnetic and diminishes the applied field in the center of the ring, but is paramagnetic and augments the applied field at the protons of the ring because they are in the return path of the magnetic lines of force [see structure (3)].

The ring-current effect makes the shift of protons attached to aromatic rings less shielded than those of protons attached to simple double bonds. One could argue that the otherwise well-known electronegativity of aromatic rings might produce the observed shifts, but this does not accord with the proton shifts of 18-annulene (**4**). This substance has a favorable 18 π -electron system and its molecular configuration is such that it has 12 *outside* and four *inside* protons attached to its carbons.

The *inside* protons, as expected from the ring-current effect, are strongly shielded and come into resonance at -1.9 ppm on the TMS scale. The *outside* protons are very deshielded and are observed at $+8.8$ ppm on the same scale. Thus, there is a difference of 10.7 ppm between the shifts of these protons.

We will have more to say about the chemical shifts of nuclei other than protons later.

Spin-spin couplings are observed between the several proton groups for ethanol, because they have different resonance frequencies. The coupling patterns are found to be variable because of the possibility of slow, or rapid, intermolecular exchange of the OH proton. With slow exchange, the OH proton is expected and found to be split into a 1:2:1 triplet by the CH_2 protons with $^3J(\text{H,H})$ equal to 4.8 Hz. Our expectation of the 1:2:1 triplet is based on the concept that there are four different kinds of molecules as far as the CH_2 magnetic states are concerned. This means that the OH proton on any given individual ethanol molecule has a 25% probability of being attached to a CH_2 carbon with proton magnetic states of total quantum number $+1$ or -1 ($+\frac{1}{2}, +\frac{1}{2}$ and $-\frac{1}{2}, -\frac{1}{2}$), and a 50% probability of being on molecules with magnetic states having quantum numbers of zero ($+\frac{1}{2}, -\frac{1}{2}$ and $-\frac{1}{2}, +\frac{1}{2}$). Generally, as noted earlier, we expect the four-bond coupling, $^4J(\text{H,H})$ to be small in most simple open-chain compounds, and for ethanol we can neglect the four-bond couplings. However, expectation that such couplings will invariably be small is not in accord with experience. The larger $^4J(\text{H,H})$ couplings are often valuable in stereochemical studies. We will have more to say about the magnitudes of spin-spin couplings after taking a look at why the OH resonance in ethanol is not always observed to be split by the CH_2 protons.

Observation of the splitting of the OH resonance in ethanol depends on whether intermolecular exchange of the OH protons is rapid compared with the lifetime of the magnetic states involved. If exchange is rapid, then any given OH proton, as it goes from ethanol molecule to ethanol molecule, runs the gamut of CH_2 groups with different magnetic states. The result is that the given OH proton experiences the average of those CH_2 magnetic states. Because the average ($+1, 0, 0, -1$) is zero, no splitting is observed when exchange is

fast compared with the lifetimes of the states. The lineshapes change between the extremes of slow and fast exchange and by analyzing those lineshapes it is possible to determine the rates of exchange as a function of solvent, exchange catalyst, or temperature with considerable precision over a range of rates amenable to exploration by few, if any, other techniques. A variant on the OH exchange studies of ethanol is to investigate the proton NMR of mixtures of ethanol with water. If a little water is added to pure ethanol, the OH resonances of the two substances are observed separately. As more water is added, OH exchange speeds up, the separate OH resonances merge and assume the weighted-average position determined by the shifts of the OH groups (if they could be determined separately for the mixture) and the relative concentrations of ethanol and water.

The proton-proton coupling patterns of ethanol under conditions of fast OH exchange are quite simple. There is a 1:2:1 group of resonances for the CH_3 group, reflecting the possible magnetic states of the two protons of the CH_2 group, and a 1:3:3:1 grouping for the CH_2 group arising from the possible magnetic states of three protons with the same resonance frequency ($+\frac{1}{2}, +\frac{1}{2}, +\frac{1}{2}$ and $+\frac{1}{2}, +\frac{1}{2}, -\frac{1}{2}$; $+\frac{1}{2}, -\frac{1}{2}, +\frac{1}{2}$; $+\frac{1}{2}, -\frac{1}{2}, -\frac{1}{2}$; and so on). The lines in each group are separated by 7.15 Hz which is the $^3J(\text{H,H})$ coupling constant. If the chemical shift difference is comparable to the coupling constant, then smaller secondary splittings may be observed. As mentioned earlier, the secondary splittings are the result of quantum mechanical influences that are most often evident in the range of shifts between the extreme, where the transitions are forbidden, because even though the coupling constant may be large, the frequency difference is zero and the other extreme where the frequency difference is much greater than the chemical shift. However, it should be recognized that there are circumstances, such as for the so-called AA'XX' nuclear spin systems, where the chemical shifts can be much larger than the couplings, but quantum effects override simple expectations of number of lines based on simply counting up the number of possible combinations of $+\frac{1}{2}$ and $-\frac{1}{2}$ nuclear magnetic states. With such systems, rather complex patterns of lines usually result.²

When OH exchange is slow, the CH_2 resonances of ethanol become complex because $^3J(\text{H,H})$ involving the OH proton is 4.8 Hz and that involving the CH_3 protons is 7.15 Hz. In effect, each of the 1:3:3:1 quartet resonances observed when OH exchange is fast now becomes, with slow exchange, split into a doublet separated by 4.8 Hz, thus producing eight resonance peaks with unequal spacings.

Much can be done to simplify and analyze spin-spin coupling patterns by either selective proton decoupling or by substituting an isotope with a different, or no, magnetic moment. Selective proton decoupling achieves the same result that we have described for ethanol consequent to OH proton exchange. What decoupling means in this context is that if we irradiate the OH protons at their resonance frequency, under slow exchange conditions, those protons cycle rapidly between the $+\frac{1}{2}$ and $-\frac{1}{2}$ magnetic states, so that their magnetic effect on the CH_2 protons is averaged to zero and, as a result, we observe the same 1:3:3:1 quartet and 1:2:1 triplet as when OH exchange is fast. Selective irradiation of the CH_3 protons will lead to a 1:2:1 triplet for the OH protons and a 1:1 doublet for the CH_2 protons with the simple splitting of 4.8 Hz. Substitution of

deuterium for the OH hydrogen, with a consequent reduction of J by a factor of 6.5, can also simplify coupling patterns.

There are many ways in which spin–spin coupling patterns can be used to solve structural problems—some of astonishing simplicity. An example is provided by a supposed tetraazodibenzocyclooctatetraene (**5**).

The hydrogens on each benzo group are expected to give NMR spectra of the AA'BB' classification with respect to their coupling patterns. However, AA'BB' patterns are always symmetrical, the resonances on the left side of the center being the mirror image of those on the right side. The problem with the supposed structure was that, in fact, the proton resonance pattern was not symmetrical and, furthermore, was too complex to be representative of AA'BB'. On this basis a different structure, shown in Scheme 1, was proposed. This is now of the ABCD type and expected to give an unsymmetrical coupling pattern.

From the description of spin–spin splitting given earlier, it might be inferred that the influence of the magnetic state of a particular nucleus on the magnetic field (and resonance frequency) of another in the same molecule is transmitted through space like an electrostatic effect. Magnetic influences of this kind are called dipolar effects and are quite large in some circumstances but, in fact, they do not contribute to spin–spin splittings for molecules in solution that are undergoing rapid tumbling. Such tumbling causes dipolar effects to be averaged to zero. What remains is the so-called scalar couplings that arise by magnetic polarization of the surrounding electrons of a magnetic nucleus and the transmission of that polarization effect through the molecule by electron delocalization in a manner analogous to the familiar resonance transmission of electrical effects.

One consequence of this mode of transmission of coupling information is to make qualitative predictions of the magnitudes of J values in many kinds of structural situations rather difficult. The one-bond coupling between the protons in dihydrogen can be calculated from the splittings in H–D and amounts to 280 Hz. A substantial amount of data is available for one-bond couplings, such as H– ^{13}C , H– ^{15}N , ^{13}C – ^{13}C , and ^{13}C – ^{15}N . The magnitudes of such splittings, particularly corresponding to $^1J(^{13}\text{C},\text{H})$ and $^1J(^{13}\text{C},^{13}\text{C})$, are valuable indicators of the hybridization of the carbons forming the bonds. The less p and the more s character to the C–H bond, the larger the coupling constant. An interesting and, in some other cases, important concern is for the signs of 1J couplings. It is not

Scheme 1

obvious how a through-space magnetic influence of one magnetic moment in a particular magnetic quantum state could, on the one hand, reduce and, on the other, augment the field at another nucleus. But with electronic transmission of the coupling influence, it is not only possible, but common, for J couplings to have different signs. For one-bond couplings, indirect methods have to be used to establish the sign and, for $^1J(^{13}\text{C},\text{H})$, the sign turns out to be positive.

Two-bond couplings, such as $^2J(\text{H},\text{H})$ of CH_2 groups, are unusually variable and dependent on the other attached groups to the carbon. Normally, $^2J(\text{H},\text{H})$ for an aliphatic or alicyclic CH_2 group will be negative and on the order of 10–12 Hz. However, when the CH_2 is part of a double bond, the coupling may be positive or negative, as well as large or small. Examples include CH_2O with $^2J(\text{H},\text{H})$ equal to +42 Hz.

Three-bond proton–proton couplings of the H–C–C–H variety are especially valuable for determination of the stereochemical relationships of groups. With protons on double bonds, the vicinal $^3J(\text{H},\text{H})$ couplings are usually much larger for *trans* relationships than for *cis* relationships. The same is also generally true for conformationally mobile systems, although the situation is much more complex; because, in principle, there is an essentially infinite range of rotational dihedral angles, θ , between the protons.

Because of its practical importance to the determination of stereochemical relationships, much theoretical and experimental research has been carried out on the relationship between $^3J(\text{H},\text{H})$ and θ in systems where the two carbons carrying the coupled protons are both saturated. Theoretical considerations suggested very early on that there should be an approximately cosine relationship between J and θ . One useful form of the equation is shown in equation (1) (see Figure 1).

$$^3J(\text{H}, \text{H}) = 7.0 - 1.0 \cos \theta + 5.0 \cos 2\theta \quad (1)$$

This curve, an example of the so-called Karplus curve, is quite satisfactory for qualitative correlations of coupling constants with stereochemistry. A variety of other relationships

Figure 1 The Karplus curve corresponding to equation (1)

Scheme 2

have been proposed because there are clear effects of the electronegativities of the attached groups on $^3J(\text{H,H})$. However, corrections for these effects still do not suffice for accurate calculations and adjustments have been offered for H–C–H and C–C–H bond angles, bond distances, and so on. Attempts to codify these couplings have led to multiparameter equations of accuracy probably not better than ± 1 Hz and, often when these equations are tried for compounds of interest, it is found that some or all of the needed parameters are unavailable, or that the calculated values of $^3J(\text{H,H})$ lead to inconsistent stereochemical results.

The areas of greatest interest in this connection are for the determination of the stereochemistry of conformationally mobile systems, of which the simplest examples are substituted ethanes. These substances are presumed to exist in more or less perfectly staggered *gauche* and *trans* conformations. A typical example might be the *gauche* and *trans* conformations of 1,1-dichloro-2,2-dibromoethane, shown in Scheme 2.

At room temperature, the rate of conformational equilibration of the respective rotamers is too fast to allow for observation of more than the averaged chemical shifts of the hydrogens. Because the chemical shift of the HCCl_2 proton is different from that of the HCBBr_2 proton, a $^3J(\text{H,H})$ coupling will be observed and if we assume, with conventional wisdom, that there are only three conformations, each most stable in the perfect staggered *gauche* and *trans* arrangements, then the experimental H–H coupling constant will depend on the equilibrium constant connecting the conformations. The system here is at its simplest because there is only one coupling constant of interest. Inspection of the conformations suggests that the one with the hydrogens *trans* to one another would seem to be the most favorable, because it has two *trans* and two *gauche* Br...Br interactions, while the other, with the hydrogens *gauche*, has one *trans* and three *gauche* Br...Br interactions.

The example of a simple Karplus curve shown in Figure 1 suggests that for $\theta = 60^\circ$ (*gauche*) the value of $^3J(\text{H,H})$ should be about 4.0 Hz and for $\theta = 180^\circ$ (*trans*) about 11.5 Hz. The two *gauche* rotamers are enantiomers and, in the absence of a chiral environment, will have the same energy. A statistical equilibrium of the three forms would have the observed coupling $(2 \times 4.0 + 11.5)/3 = 6.5$ Hz. The experimental value is 3.0 Hz. Because this value is even smaller than that estimated for the *gauche* conformations exclusively, it is clear that something is amiss. One unknown is whether or not the conformations will assume perfectly staggered angles. If we solve equation (1) for the rotational angles that give 3.0 Hz for the H–H coupling constant, we get 68.2° and 105.6° as possible values. These angles can be seen to have the advantage of moving two pairs of halogens farther apart at the cost of bringing another pair closer together. The 68.2° rotational angle does this less extremely and intuition suggests that this is a possible solution to the conformational problem (Scheme 3).

Scheme 3

However, we have alluded earlier to the need to correct the couplings for the electronegativity of substituent groups and, in general, strongly electronegative groups such as halogens make the couplings smaller. A multiparameter equation³ that relates couplings to rotational angles and takes into account substituent electronegativities estimated by the Huggins procedure suggests that the *gauche* and *trans* couplings of the perfectly staggered conformations of 1,1-dichloro-2,2-dibromoethane should be 2.2 and 6.4 Hz, respectively. These figures suggest that the *gauche* form dominates to the extent of 81%. The overall level of uncertainty in the conformational analysis even for this very simple example is large, but at least the message is consistent that the *trans* conformation is not as favorable as the *gauche*.

Determination of the conformational equilibrium or stereochemical configuration for ethanes in general, or for other two-carbon fragments with more than two hydrogens, is often made difficult because of the need to perform a computer analysis to extract the vicinal coupling constants from complicated spin–spin coupling patterns. Such analyses can be carried out in several ways; one that has reasonably stood the test of time is the program LCN3, originally written in FORTRAN for IBM computers using punched-card input.⁴ With this program, intuition and experience are called upon to input trial shift and coupling parameters that produce a sample spectrum to compare with the experimental spectrum. If there is reasonable correspondence, the user correlates and enters the experimental line positions with particular transitions calculated from the trial parameters. The computer program then attempts to find the best fit between parameters, the calculated and the experimental line positions for the given transition assignments. A second or third round of transition assignments is often required to give an rms fit between calculated and experimental line positions on the order of 0.2 Hz.

Consider now a 1,2-disubstituted ethane—once one has determined the coupling constants that correspond to its experimental proton spectrum, there is still the problem of obtaining a set of predicted couplings to compare them with to estimate the position of the conformational equilibria. Assuming only the conventional staggered conformations, it can be seen that there are two different vicinal couplings, J_t^g and J_t^t for the *trans* rotamer and four different vicinal couplings for the two energetically equivalent *gauche* rotamers, J_g^t , J_g^g , J_g^{gt} , and J_g^{gg} (see Scheme 4).

In this context, we use subscripts on the J s to denote the conformational family and superscripts to define the relationships between the coupling hydrogens. Matters become much more complex if X and Y are chiral groups, but we shall ignore that possibility here.

Scheme 4

Scheme 5

Empirical relationships allow an estimation of all of these couplings and, in practice, rapid interconversion of the conformations averages some of these couplings for the *gauche* rotamers. If we number the hydrogens of the *gauche* rotamers, we will see that interconversion of these rotamers will cause $J(1,4)$ and $J(2,3)$ to be the average of J_g^t and $J_g^{g''}$. Similarly, $J(1,3)$ and $J(2,4)$ will be the average of J_g^g and $J_g^{g'}$ (see Scheme 5).

Unless the two-bond geminal H–H couplings are different, they will have no influence on the appearance of the spectra.

An illustrative and instructive example of the use of vicinal couplings in the conformational analysis of 1,2-disubstituted ethanes is for butanedioic acid, where X and Y are both carboxy groups. Having X and Y equivalent groups simplifies matters by making J_g^g and $J_g^{g'}$ equivalent, but also complicates them because now the chemical shift difference between the CH₂ groups disappears. With no chemical shift difference, the vicinal couplings become invisible. This part of the problem can be solved with the aid of ¹³C labeling of one or both CH₂ groups, or by utilization of natural abundance ¹³C, although this is only present to the extent of 1.11%. With a ¹³C at one CH₂ group, the proton spin system becomes AA'BB'X and, with two ¹³C atoms, it is AA'BB'XX'. In either case, the effect of the rather large $^1J(^{13}\text{C},\text{H})$ coupling (~125 Hz) is to produce a complex proton spectrum from which the vicinal H–H couplings can be extracted.

The chemical interest in the conformational analysis and conformational preferences of butanedioic acid stems from the assessment they allow of the role of hydrogen bonding and electrostatic interactions between the carboxy groups as a function of pH, wherein by changing the pH we can have species with two –CO₂H, one –CO₂H and one –CO₂[–], or two –CO₂[–] groups. Definition of the parameters of the system requires a substantial number of determinations of the changes in the vicinal couplings with pH, especially in the intermediate region where all three species exist in significant quantities. With these, it is possible to calculate the couplings of the monoanion, if it is reasonably assumed that the couplings of the unionized acidic and the dianionic species are invariant with pH and can be determined at low and high pH, respectively.

The results are interesting in that they indicate that the unionized acid prefers the *gauche* conformations to the extent of about 80%, the monoanion [perhaps expected to be highly internally hydrogen bonded and strongly favoring *gauche* (6)] exists actually somewhat less as the *gauche* rotamer

(65%), and the dianion (where electrostatic repulsions might be expected to lead to a high percentage of the *trans* conformation) is only about 50% *gauche* and 50% *trans*.⁵

The type of procedures using vicinal coupling constants described here has very general utility in the determination of conformations and conformational equilibria in a wide variety of acyclic and alicyclic compounds. For complex molecules, the proton spectra may be so complicated that it is not easy or straightforward to determine which protons are coupled to which, much less analyze the coupling patterns. In such cases, two-dimensional spectra can be very helpful. It might seem that ordinary spectra are two dimensional in that we have one dimension of frequency and another of intensity. In NMR, what we call two-dimensional spectra are, in that sense, three dimensional—two dimensions of frequency and a third of intensity. But it is two dimensions of frequency, not of intensity, that we actually call attention to in the usual nomenclature. For the problems of sorting out H–H couplings, a technique called COSY (CORrelated Spectroscopy) is especially useful. It does not give the coupling constants itself, but does show which protons, or groups of protons, are coupled to each other. The usual presentation is a graph such as Figure 2, where the observed proton resonances are plotted along the horizontal and vertical axes and the chemical shifts are found along the diagonal. The coupling interactions between the protons show up as peaks,

Figure 2 A two-dimensional COSY proton spectrum of ethanol. The purpose of the COSY spectrum is to show which proton groups are coupled to which other groups. Here we can see that the diagonal peaks correspond to the chemical shifts and the off-diagonal peaks to the spin–spin interactions of the OH and CH₂ protons, as well as to those of the CH₂ and CH₃ protons. The lack of coupling is also clear for the OH and CH₃ protons

Scheme 6

or contours of peaks (depending on the plotting mode) off-diagonal, and can be correlated with the respective resonances plotted along the axes.

A very important use of NMR is for the measurement of rates of conformational equilibration and the classic case of the use of NMR for this purpose is *N,N*-dimethylmethanamide. Resonance theory suggests that this, and related, molecules are most stable with the planar amide configuration having a substantial measure of double-bond character to the C(O)–N bond (Scheme 6). The resonance stabilization energy calculated from bond energies and heats of combustion is usually about 79 kJ mol^{-1} (19 kcal mol^{-1}) and presumably all of this stabilization is lost at the midpoint of rotation about the C(O)–N bond.

N,N-Dimethylmethanamide shows two CH_3 proton resonances at room temperature, which demonstrates that rotation must be slow because rapid rotation would interchange the chemical shifts of the methyl groups. On heating, the separate methyl proton resonances first move closer together, because raising the temperature increases the rocking motion about the C(O)–N bond, and this decreases the chemical shift difference. Then, when the rate of surmounting the rotational barrier becomes great enough to affect the lineshapes, the methyl proton resonances broaden, coalesce, and finally narrow.⁶ The actual temperature at which coalescence just occurs is called the *coalescence temperature* and the rotational rate which corresponds to it is given by equation (2), provided that one knows (normally by extrapolation) both the chemical shift difference, $\Delta\delta$, and the corresponding linewidths that protons would have at the temperature of the coalescence point, if rotation were slow.

$$k = \frac{\pi \Delta\delta}{\sqrt{2}} \quad (2)$$

Equation (2) is not accurate if the linewidths are comparable to the shift difference. Clearly the coalescence temperature will change with the spectrometer frequency, because $\Delta\delta$ will change with the spectrometer frequency.

The activation energy, E_a , obtained from a number of studies of the changes in linewidth and coalescence of the methyl group resonances of *N,N*-dimethylmethanamide with temperature, was originally subject to large experimental errors, but is now agreed to be close to 83 kJ mol^{-1} (20 kcal mol^{-1}), in good agreement with the calculated loss of resonance energy at the midpoint of rotation about the C(O)–N bond.

In many studies, the chemical shift differences and linewidths are taken to be those measured at temperatures quite different from the coalescence point and this can lead to serious errors. There are other, and very useful techniques, for measuring rates of processes, such as restricted rotation by NMR.^{7–9} In some cases, chemical shift differences are averaged; in other cases, coupling constants are averaged and, most often, both are involved. One excellent example of coupling

constant averaging alone is provided by the hydroxy proton of ethanol as described earlier.

A quite different type is observed with 3,3-dimethylbutylmagnesium halides (7). Rotation is rapid, but the large *t*-butyl and MgX groups strongly prefer to be *trans* to one another. The two CH_2 groups are then expected to form an AA'XX' spin system. However, at room temperature, one observes a typical triplet A_2X_2 spectrum. This is because the MgX group, by one mechanism or another, changes its configuration at C-1. The configurational change is accompanied, or followed, by a C–C bond rotation that causes the A and A' protons to exchange positions. At -53°C , a sharp AA'XX' spectrum is observed and, from the spectral changes with temperature, it is possible to determine the activation energy, E_a , for the change in configuration at C-1.¹⁰

NMR has proved extraordinarily useful in determining the rates and positions of conformational equilibria in cyclic compounds of which cyclohexane (Scheme 7) is the prototype.

Unfortunately, cyclohexane itself, although giving only a single sharp proton resonance when equilibration is fast, provides a difficulty manageable complex splitting pattern when equilibration is slow. One elegant solution (Scheme 8) is to substitute deuterium for 11 of the hydrogens and remove the residual small H–D couplings by irradiating the deuteriums at their resonance frequencies.¹¹ This procedure leads to a sharp single proton line when interconversion is fast, and two chemically shifted lines, one for axial and one for equatorial protons, when interconversion is slow. An analogous, and also elegant, procedure is to label with tritium and irradiate the protons while observing the tritium spectrum. From the changes of lineshape with temperature, the activation energy for interconversion of the chair forms of cyclohexane has been found to be about 46 kJ mol^{-1} (11 kcal mol^{-1}). For many ring compounds, conformational equilibria can also be usefully studied by labeling with fluorine, which has 10–20-times larger chemical shift differences than protons when in comparable conformational situations but does not make much difference to the rates or activation parameters. Thus, changes in the ^{19}F spectrum of 1,1-difluorocyclohexane as a function of temperature give nearly the same E_a as with cyclohexane itself.¹²

Techniques such as these have been applied to a wide variety of mono- and polycyclic ring systems. They give information on such diverse situations as the degree of the flexing of cyclobutane rings to inversion barriers for cyclooctanes and for *cis*-decalins.

Scheme 7

Scheme 8

Another and more subtle use of NMR in stereochemical analysis has to do with what are called *diastereotopic* atoms or groups. A simple example is afforded by diethyl sulfite (8).

At first glance, this substance might be expected, like ethanol with rapidly exchanging OH protons, to give a 1:3:3:1 quartet for the CH₂ protons and 1:2:1 triplet for the CH₃ protons. The CH₃ protons, in fact, do show the expected 1:2:1 triplet, but the CH₂ protons give 16 resonances corresponding to four 1:3:3:1 quartets. The reason for this rather striking behavior is that the sulfite group is nonplanar and, as a result, the CH₂ protons on the same carbon are not equivalent by symmetry and are designated as diastereotopic. This phenomenon shows up in many kinds of compounds and can be used to determine the rates of conformational changes. One superb example is in the measurement of the inversion rates of a substituted cyclooctatetraene that exists most favorably as a 'tub' structure (Figure 3).

Figure 3 Interconversions of cyclooctatetraene conformations. At the top and bottom are shown the result of simple ring inversion without shift of the double bonds, while the vertical center equation represents inversion with bond shifts, as expected for something approximating a planar pseudoaromatic structure

It will be seen that the CH₃ groups are diastereotopic and if, as shown in Figure 3, the C₈ ring simply inverts, then the CH₃ groups interchange their positions. Thus, if inversion is fast in the NMR time sense, the methyl groups will be equivalent. Note, however, that this process makes no change in the status of any of the ring hydrogens relative to their neighbors. On the other hand, if the ring were to flatten and the double bonds shift, then the hydrogens next to the substituent group would change their relationship to the substituent. For the ring H shown in Figure 3, what is shown as a ring double bond between its carbon and the carbon carrying the dimethylhydroxymethyl group then becomes a single bond, so that there will be both chemical shift and coupling changes for this H. Analyses of the changes in lineshapes of the diastereotopic methyl groups, and of the ring hydrogens, provide a measure of the rates of both ring inversion and bond shifts. It turns out that both processes occur at roughly comparable rates.¹³

In the examples described here and earlier, it should be evident that NMR offers unique possibilities to probe processes that are of great theoretical and practical interest.

The NMR of other nuclei commonly found in organic compounds have also had an enormous impact on studies of organic structures and dynamic properties. Most prominent among these (all spin- $\frac{1}{2}$) nuclei are ¹³C, ¹⁵N, ¹⁹F, and ³¹P. Each of these nuclei has one important characteristic that is not shared with hydrogen. That is, their usual ranges of chemical shifts in ppm exceed those of hydrogen by a factor of 10 to 20. The reason for this is clearly connected to the fact that the elements corresponding to these nuclei form bonds to other atoms using p orbitals while hydrogen uses s orbitals. With p orbitals, the *second-order paramagnetic effect* becomes important whereby electron circulation through high-energy orbitals, mixed with the normal ground-state orbitals, is induced by an applied magnetic field to increase the ground-state stability and, at the same time, decrease the nuclear shielding. This effect, which acts to reduce the shielding at the nucleus of the oxygen of an alcohol and thus allows rationalization of the substantial shielding observed of the OH proton when hydrogen bonding is decreased, as mentioned earlier.

We have alluded to the usefulness of ¹⁹F as a label for hydrogen in conformational analysis and equilibration. This is a small benefit compared with the paramount importance of ¹⁹F spectra through determination of shifts and couplings for the establishment of the structures of fluorocarbons and halofluorocarbons for which there are very few other useful techniques.

Phosphorus occurs much less commonly in organic compounds as a multiple substituent than do fluorines, but ³¹P NMR has wide utility in the study of organophosphorus compounds and of organophosphorus ligands in metal complexes.

The NMRs of carbon and nitrogen are of special interest to organic chemistry in general, but unfortunately are not as easy to observe as those of ¹H, ¹⁹F, and ³¹P. The relevant isotopes are ¹³C, ¹⁵N, and ¹⁴N. Of these, the last has a high natural abundance (99.63%) but a resonance frequency of about $\frac{1}{14}$ that of ¹H and, much worse, a spin of 1. The problem with nuclei having spins greater than $\frac{1}{2}$ is that they have electric quadrupole moments, in effect their nuclear changes are not spherically symmetrical. The result is that whenever the electron distribution around the nuclei is not spherically

symmetrical, rotational motions can create an electrostatic torque which causes the nuclei to change their magnetic orientation, i.e. to relax. This form of relaxation has a variable efficiency. It depends on the magnitude of the nuclear–electric quadrupole moment, on the degree of electrical dissymmetry, and also on the spectrum of rotational motions. For ^{14}N , the resultant of these factors is such that quadrupole relaxation is usually quite serious and the ^{14}N NMR linewidths may be more than 200 Hz wide. Because nitrogen has about a 900 ppm range of chemical shifts, which at 35 MHz (500 MHz for ^1H) amounts to 32 000 Hz, much can be done with ^{14}N NMR in terms of measuring chemical shifts, even with large linewidths.

There are important effects of ^{14}N on proton spectra. The coupling between ^{14}N and a directly attached (nonexchanging) proton is normally about 60 Hz. In the absence of fast relaxation, a 1:1:1 triplet with a 60 Hz splitting would be expected for a nonexchanging ^{14}N –H proton. Except for ammonium ion, which has a spherical symmetrical charge distribution, the lines making up these splittings are more or less broadened to the point of being unrecognizable. Of course, the relaxation rates of the ^{14}N nuclei that cause these effects are the same as those that cause broadening of the ^{14}N resonance signals themselves. Thus, for some substances such as pyrrole, their N–H proton resonances are often so broad that they can only be made clearly visible by integration.

Similar difficulties arising from rapid quadrupole-induced relaxation are usually encountered in the NMR of other nuclei with spins greater than $\frac{1}{2}$, such as ^2H , ^7Li , ^{11}B , ^{17}O , and ^{33}S . With some of these nuclei, particularly ^{17}O and ^{33}S , the difficulties are exacerbated by very low natural abundances and low availability of isotopically enriched materials.

For obvious reasons, carbon NMR has received much attention over the years. The abundant isotope ^{12}C (98.9%) has no spin, which can be regarded as a blessing because it avoids the complexities in proton spectra that would be associated with C–H and C–C couplings. The less-abundant ^{13}C (1.11%) has spin- $\frac{1}{2}$ and has a resonance frequency about one-fourth that of protons. In the initial days of NMR, ^{13}C could only be usefully observed with isotopically enriched samples. The first ‘routine’ ^{13}C spectra were taken by Lauterbur¹⁴ using a special technique called ‘adiabatic rapid passage’ and these spectra, while lacking in resolution, made very clear the enormous potential importance of ^{13}C for structural analysis.

The next great step forward was made by Grant and co-workers¹⁵ in which they demonstrated the utility of proton decoupling to simplify ^{13}C spectra and the importance of the nuclear Overhauser effect (NOE) attendant to proton decoupling to enhance the intensity of the decoupled signals.

Following on the heels of these advances came the introduction of stable enough NMR spectrometers to allow time averaging of signals, pulse Fourier transform procedures, and proton noise decoupling to simplify and enhance the spectra. The result was that only a few short years passed before ^{13}C NMR became a truly routine procedure for structural analysis.

The level of natural abundance of ^{13}C works to the advantage of the ^{13}C , as well as the ^1H , spectroscopist. If ^{13}C were highly abundant, ^{13}C – ^{13}C couplings would enormously complicate the spectra and would require difficult homonuclear decoupling to simplify the peak patterns for structural analysis. With the probability of having two ^{13}C atoms per molecule being on the order of 0.01% in the absence of isotopic

enrichment, it can be seen that ^{13}C – ^{13}C couplings will not offer much complication of ^{13}C spectra. However, it is possible to detect such couplings by time averaging and they provide valuable structural information. Thus, the INADEQUATE procedure,¹⁶ although requiring relatively larger amounts of sample than an ordinary ^{13}C spectrum, detects all of the one-bond ^{13}C – ^{13}C couplings in a molecule and clearly shows which carbons are connected to which; in effect directing how the C–C bonds should be drawn. If, when using this procedure, a carbon resonance exhibits no ^{13}C – ^{13}C coupling, it must be part of a CH_3O , CH_3N , or the like type of grouping.

One of the very useful characteristics of ^{13}C NMR is the sensitivity of carbon shifts to steric hindrance. An axial methyl group on a cyclohexane ring has a smaller shift relative to TMS than an equatorial methyl. Thus, for a methylcyclohexane (9) with a *cis* 4-R group that is larger than CH_3 , a *t*-butyl group is excellent, the ^{13}C shift of the methyl, of C-1, and C-3, C-5 are on the order of 4–6 ppm more shielded than the corresponding carbons in the *trans* isomer.¹⁷ This is a very general phenomenon and is vividly evident in the steroids, where there are usually multiple 1,3-diaxial interactions of the angular methyl groups with *trans* A,B and C,D ring junctions.

The sensitivity of ^{13}C shifts to steric interactions is a tremendous boon for the study of polymers. For example, solutions of the isotactic, syndiotactic, and atactic forms of polypropene give quite different ^{13}C spectra and it is very easy to determine the purity of isotactic polypropene by ^{13}C NMR.¹⁸ Another characteristic of ^{13}C that is favorable for the study of polymers is that its large chemical shifts permit use of more viscous samples than is usually the case for ^1H spectra. Thus, natural rubber has sufficient molecular motion that its ^{13}C spectrum can be obtained without being dissolved in a solvent.

Another area where ^{13}C NMR has proved invaluable is in the study of the structures and dynamic interconversions of carbocations. In earlier days, the existence and properties of such ions were inferred from kinetics, stereochemical changes, and skeletal rearrangements. The exception was the triphenylmethyl (trityl) cation which could be studied spectroscopically (including by NMR) in concentrated sulfuric acid solutions. The reason that the trityl cation can be obtained in high concentration in strong enough acid is that this cation is stabilized sufficiently by resonance so that it does not react with the weakly nucleophilic HSO_4^- counterion. To form less stable carbocations requires solvent systems with still less nucleophilic counterions and this objective has been achieved by Olah with his ‘magic acid’ solutions concocted of mixtures of such substances as SbF_5 , SO_2FCl , and SO_2F_2 . In such media, stable carbocation solutions can be formed, usually at temperatures well below 0°C that give excellent and enormously interesting NMR spectra.¹⁹

For example, the norbornyl cation (Scheme 9), whose structure has been the subject of vigorous debate for more than 40 years, shows only one ^{13}C resonance at room temperature.

Figure 4 The upper left equation shows a 1,2-carbon shift of the Wagner–Meerwein type that would be expected for a simple ‘classical’ norbornyl cation. The rearranged cation is the mirror image of its precursor. If just these cations were in rapid equilibrium with each other, or had the nonclassical structure shown in Scheme 9, then the ^{13}C spectrum should show five different resonances in the ratio 1:1:1:2:2. That only one ^{13}C resonance is found at room temperature shows that there must be additional fast rearrangements involving 2,3-, 6,2-, and 6,1-H shifts. At -70°C , the 2,3-H shifts are slow and at around -140°C the 6,2- and 6,1-H shifts become slow, so that only the 1,2-C shift operates or the structure shown in Scheme 9 is correct

To account for this result, on the basis of the classical structures shown in Figure 4, a primary contributor has to be very rapid 1,2-C shifts wherein C-6 changes from being bonded to C-1 to being bonded to C-2 and the reverse. Such shifts are examples of the well-studied Wagner–Meerwein carbocation rearrangements and, in this case, the original and rearranged cation have carbon skeletons that are mirror images of one another. If only 1,2-C shifts occurred, then one would expect five ^{13}C resonances in the ratio of 1:1:1:2:2 rather than the observed single resonance. So we have to call on somewhat less common hydride rearrangements from C-2 to C-3 and from C-6 to C-2 or C-6 to C-1 shown in Figure 4. If all of these hydrogen migrations and the 1,2-C shifts are fast, then only a single ^{13}C resonance is expected.²⁰

Lowering the temperature to -70°C causes the 2,3-H shifts to slow down and then one observes the three ^{13}C resonances suggested by the combination of fast 1,2-C, 6,2-H, and 6,1-H shifts as shown in Figure 4. Further cooling to about -140°C causes the 6,2- and 6,1-H shifts to become slow.^{20–22} Further cooling, even to liquid helium temperatures,²² does not give seven ^{13}C resonances and there seems no question that the actual structure of the norbornyl cation is the bridged ‘nonclassical’ formulation (Scheme 9) postulated many years earlier from kinetic and product studies.

A very similar, but not as well-resolved, situation involves the C_4H_7^+ cation(s) that are intermediate in the carbocationic interconversion reactions of cyclopropylmethyl, cyclobutyl, and 3-butenyl derivatives.^{19,23} Here, the ^{13}C NMR in ‘super acid’ solutions shows two ^{13}C resonances in the ratio 1:3. Lowering the temperature to -132°C causes changes in the shifts, but not in the multiplicity of lines, indicating that there is a fast equilibrium involving more than one cationic species.²⁴ On further cooling, Myhre and co-workers²⁵ have found that further ^{13}C spectral changes occur at about -210°C which

Scheme 9

Scheme 10

correspond to slowing of the interconversion between the cationic species. Then, with continued cooling, the position of the equilibrium apparently shifts and, at liquid helium temperatures, there may well be only one nonclassical cationic species present with four nonequivalent carbons.

Another very interesting and potentially useful technique in the study of fast equilibria has been provided by the Saunders ‘isotopic-perturbation’ procedure.²⁶ In the study of carbocationic equilibria as described above for the norbornyl and C_4H_7^+ cations, there is always the question as to whether there is an equilibration between ‘classical’ structures or a stable ‘nonclassical’ intermediate. The formulas in Scheme 10 show a cation that involves either rapid 1,2-hydrogen shifts or has a hydrogen-bridged structure.

The ^{13}C resonances of C-1 and C-2 (Scheme 10) are equivalent in the absence of the deuterium labels and this means either that equilibration is very fast or that the bridged structure is stable. The Saunders technique involves substitution of just one of the methylene groups with deuterium as shown in Scheme 10. If there is fast equilibration and the bridged ion is unfavorable, then the deuterium should exert a sizable secondary isotope effect on the position of the equilibrium and thus change the relative C-1 and C-2 ^{13}C shifts. On the other hand, if the bridged ion is the important cationic intermediate, then there is little equilibration and the relative ^{13}C shifts changes with deuteration should be small. Experimentally, quite large changes in ^{13}C shifts are observed, but much smaller ones for the norbornyl and C_4H_7^+ examples discussed above.

Another very important use of ^{13}C NMR is for tracing biosynthetic pathways to aid in unraveling the mechanisms by which organisms achieve the myriad of transformations important to living systems. This can also be done with the radioactive isotope of carbon, ^{14}C , but to do so usually requires difficult and lengthy degradation procedures to determine specific positions of labeling. If the ^{13}C spectrum is known of the metabolite under investigation, ingestion of a suitable enriched ^{13}C precursor will result in greatly enhanced ^{13}C resonances, wherever the biosynthetic transformation puts a ^{13}C from the precursor into specific positions in the metabolite.

Another useful procedure in biosynthetic tracing is to use a precursor with adjacent doubly labeled ^{13}C positions where the level of enrichment is sufficiently high to make the ^{13}C – ^{13}C coupling easy to detect. Now, if this labeled precursor is mixed with an unlabeled precursor, then it is possible to tell from the persistence or nonpersistence of the coupling whether or not the ^{13}C – ^{13}C bond is broken apart and later reassembled with the possibility of formation of ^{13}C – ^{12}C bonds, where the ^{12}C comes from the corresponding position in the unlabeled precursor.

Many of the ways of using ^{13}C are also adaptable to ^{15}N . The major problem with natural abundance ^{15}N NMR is that ^{15}N is present only to the extent of 0.37% in ordinary nitrogen. These numbers mean that ^{15}N is on the order of 2×10^5 times more difficult to obtain a useful signal than with ^1H .

This in no way means that natural abundance ^{15}N NMR is impossible. With the aid of time averaging and rather larger samples than are normally used with proton NMR, a substantial body of information on chemical shifts, couplings, relaxation times, and exchange rates has accumulated. At the natural abundance level with a modern high-field spectrometer, a reasonable spectrum can now be expected to be obtained in an hour or two in a 10-mm sample tube, if the nitrogen atoms of interest are present in 0.1 M concentration. Such expectations may not be realized because the T_1 relaxation times of ^{15}N , while highly variable, tend to be longer than those of ^{13}C and this can mean a substantial waiting time for the restoration of the Z-axis magnetization in taking time-averaged ^{15}N spectra. In some situations, it may be useful to add a small amount of a paramagnetic relaxing agent, such as the tris-chromium enolate salt of 2,4-pentadione, to shorten T_1 and to permit more rapid pulsing. However, shortening T_1 by adding a paramagnetic relaxing agent can be distinctly unhelpful, if it is hoped to develop a sizable NOE by proton decoupling. Development of a NOE by proton decoupling leads to positive enhancement of ^{13}C resonances. If the ^{13}C peak is split into a simple doublet by a single attached proton, decoupling of this proton will collapse the splitting making the signal twice as strong. The NOE then enhances the signal by another factor of three giving a total gain in peak height compared to one of the doublet peaks of a factor of six. This is a matter of great importance in the battle for higher sensitivity in the NMR detection of ^{13}C resonances.

The development of ^{13}C NOE by proton decoupling requires that the nucleus, whose resonance is being enhanced, relax by the T_1 path of so-called 'dipolar relaxation' involving the decoupled protons. Incursion of other relaxation modes, such as induced by paramagnetic ions, either diminishes or, if highly efficient, eliminates the NOE. With ^{13}C , the loss of NOE is serious but, at worse, the signal strength will be down by a factor of three to that expected for just removal of the splitting.

The situation with the NOE of ^{15}N is more complicated. The ^{15}N nucleus has a *negative* gyromagnetic ratio. This means that the ordering of the nuclear magnetic energy levels is different and the NOE is negative. A full NOE makes for an *emission* signal that is eight times more intense than either half of a doublet caused by a ^1H - ^{15}N coupling. A partial NOE can turn out with ^{15}N to be worse than no NOE at all because, as one proceeds from a full NOE to no NOE, the negative signal becomes weaker, goes to zero, and then becomes positive. For this reason, a paramagnetic relaxing agent may well do more harm than good if the advantage of a ^{15}N NOE is desired.

It turns out that when molecular motions are slow, dipolar relaxation becomes inefficient compared with other mechanisms and this will cause the NOE to diminish or disappear. When ^{15}N spectra are taken of very large molecules, such as enzymes or tRNA, with proton decoupling, the resonances of the nitrogens on side chains that have substantial mobilities will be large and negative, while those in less mobile positions will show the effects of partial or no NOE. Raising the temperature to increase the rates of molecular motions then causes the nitrogen resonances of substances like these to increase, or decrease, in intensity depending on whether they were positive or negative before the increased NOE became effective.

There is a fine line to tread here with respect to long T_1 values and the loss of NOE. In general, large molecules have

slower motions that lead to smaller T_1 values for ^{15}N than do small molecules with similar kinds of nitrogens. The shorter is T_1 , the more efficiently one can perform time averaging. However, as mentioned, if the molecular motions become too slow, dipolar relaxation becomes inefficient and the NOE decreases. This combination of factors suggest that the ^{15}N T_1 of small molecules could be reduced and the efficiency of time averaging improved by any means that increases the viscosity of the solvent without losing NOE, until that point is reached where dipolar relaxation becomes inefficient.²⁷

Nitrogen-15 NMR shifts of saturated amines closely parallel the ^{13}C shifts of analogously substituted carbon compounds. Thus, the ^{13}C resonance of a methyl group in 2,2-dimethylpropane correlates with the ^{15}N resonance of 2-amino-2-methylpropane. The ^{15}N shifts of primary, secondary, and tertiary amines fall on different linear correlation lines with the tertiary amines having the greatest scatter. Once unsaturation is introduced in the molecules, the correlation fails. Thus, the points for the ^{15}N shift of aminobenzene and the ^{13}C shift of the methyl in methylbenzene do not come close to the saturated primary amine correlation line.²⁸ The reason for this is that whereas the nitrogen lone pair can be delocalized into the unsaturated system, there is no electron lone pair available on the methyl group.

While there are many applications of ^{15}N NMR paralleling those of ^1H and ^{13}C , one rather special attribute of the chemical shifts of nitrogen is their sensitivity to hydrogen bonding and protonation, particularly if the nitrogen is part of a double bond or an aromatic ring. For example, the ^{15}N shift of azabenzene (pyridine) changes about 38 ppm in going from a poor hydrogen-bonding solvent (cyclohexane) to an excellent hydrogen-bonding solvent (trifluoroethanol). Outright protonation causes an overall shift of about 98 ppm.²⁹

A very interesting aspect of both the hydrogen bonding and the protonation shifts is that they correspond to *increased* shielding of the unsaturated nitrogen. This is exactly opposite to what happens to the OH proton which experiences decreased shielding through being involved in hydrogen bonding. The explanation for this is through operation of the second-order paramagnetic effect mentioned earlier. The unprotonated or unhydrogen-bonded nitrogen has an unshared electron pair. In a magnetic field, the molecule gains some measure of stability through the paramagnetic circulation of one of those unshared electrons in an excited-state orbital. Hydrogen bonding or protonation is expected to diminish this paramagnetic circulation by making it electrostatically less favorable to promote one of the unshared electrons to a higher orbital.

An illustrative example of the use of ^{15}N NMR to study the state of molecules in solution is afforded by comparing the pH dependences of the ^{15}N spectra of the nitrogens of the imidazole rings of histidine³⁰ and the *cis* and *trans* isomers of urocanic acid (Scheme 11).³¹

Unprotonated imidazoles have two rapidly interconverting tautomeric forms and customarily, if there is a single substituent at C-4, that form is favored which has N-1 as an NH group (Scheme 12).

Because of the nature of the nitrogens, one being to a first approximation $\text{C}=\text{N}$ —and the other being $\text{C}-\text{NH}$ —, we expect and find a large ^{15}N chemical shift difference. However, the observed shift difference is expected to depend on the position of the tautomeric equilibrium. If the equilibrium constant is

Scheme 11

Scheme 12

near unity, then the difference will be small, if it is large then the shift difference should approach the difference in ^{15}N shifts of *N*-methylimidazole (83 ppm).³² Thus, the shift difference can tell us something about the position of the equilibrium and the effect of R on it. 4-Methylimidazole shows a shift difference of 8.4 ppm and if we neglect the relatively small electrical effect of the methyl group on the individual shifts then we can calculate that the tautomer with N-1 as the NH is about 55%.

Figure 5 shows the pH dependences of the ^{15}N chemical shifts of the subject compounds. Histidine loses three protons over the pH range while the urocanic acid isomers lose two protons. The simplest case is of the *trans*-urocanic acid which at the lowest pH has the carboxy group unionized and the imidazole group protonated. It will be seen from Figure 5 that when both imidazole nitrogens are protonated there is little difference in their ^{15}N chemical shifts. The carboxy group being *trans* has no opportunity to flirt in an intramolecular fashion with the nitrogen of the imidazole ring and would not anyway when the carboxy group is unionized. When the pH is increased to about 4, the carboxy becomes ionized but the imidazole remains protonated. Here again, the carboxy

Figure 5 Changes of ^{15}N chemical shifts of *trans*-urocanic acid (----), *cis*-urocanic acid (— —), and histidine (—) as a function of pH. The numbering of the nitrogens follows Scheme 12

Figure 6 The principal structures of *cis*-urocanic acid expected, from left to right, in strong acid, neutral, and basic solutions, as well as the hydrogen bondings expected for the latter two which help to account for the ^{15}N shift changes seen in Figure 5

group is not positioned so as to be able to get close to and influence the nitrogens in the same molecule. There is little change in the ^{15}N chemical shifts until, between pH 4 and 8, the imidazolium cation loses its proton. At this point, the fast tautomeric equilibrium (Scheme 12) comes into play and the shift difference of 36 ppm at high pH suggests that the tautomer with N-1 as the NH amounts to 72%, larger than for 4-methylimidazole, but by a ΔG difference of only about 1.7 kJ mol^{-1} ($0.4 \text{ kcal mol}^{-1}$).

The *cis* isomer behaves quite differently after the ionization of the carboxy group at about pH 4. Now, as shown in Figure 6, the *cis* orientation at the double bond allows the carboxylate group to swing around and hydrogen bond to the proton on N-3 of the imidazolium cation. This interaction causes the N-3 to become somewhat less shielded than N-1 and creates a moderate chemical shift difference. Further increase in pH causes the imidazolium cation to lose a proton and the carboxy group can now hydrogen bond with the tautomer having N-3 as the NH, thus moving the tautomeric equilibrium from its usual position favoring N-1 as the NH nitrogen. This has the effect of making N-1 the less shielded nitrogen and N-3 the more shielded nitrogen and, at the higher pH values, about 82% of the material has N-3 as the NH nitrogen. It is interesting that the electrostatic effect of the carboxylate group and/or its hydrogen bonding to the proton on N-3 makes the imidazole ring a stronger base by about 0.9 pK units.

The behavior of the ^{15}N shifts of *cis*-urocanic acid has a very close parallel in the behavior of the corresponding pH shifts of the ^{15}N resonances of the histidyl residue making up part of the 'catalytic triad' at the active site of α -lytic protease.³³ In this substance, the role of the urocanic carboxy group is taken by the free carboxy of an aspartate residue, which although many residues distant from the histidine, is held in close proximity by the folding of the peptide chains.

The pH dependences of the ^{15}N resonances of the imidazole nitrogens of histidine itself (see Figure 7) are more complicated because the α -amino group is not tied up in a peptide bond, as it is for the histidyl group at the active site of α -lytic protease. Further, free histidine has one more proton to ionize. In the low pH region, the N-1 and N-3 ^{15}N resonances are close together as before. When the carboxy ionizes, there are smaller, more subtle, changes in the shifts than for *cis*-urocanic acid. These can be rationalized on the basis that the positively charged ammonium group makes hydrogen bonding of the carboxylate group to the N-3 proton less favorable than for *cis*-urocanic acid. Furthermore, the loss of the imidazolium proton in the next step is more favorable than for *cis*-urocanic acid, because with the *cis* acid the proton is lost from a neutral entity while with histidine it is lost from a positive entity. However, when that proton is lost, there is a competition between the carboxylate hydrogen bonding to the tautomer with NH at N-3 and the ammonium group undergoing hydrogen bonding to

Figure 7 The tautomers and their hydrogen-bonded structures of histidine as a function of the protonation level

the tautomer with N-3 as C=N-. The ^{15}N shifts show that the latter possibility wins out, giving about 83% of the tautomer with N-1 as NH. Then, when the pH is increased further and the proton is removed from the ammonium group, there is a shift of equilibrium to about 64% of the tautomer with N-1 as NH. That this tautomer is favored, but the equilibrium is on the opposite side with *cis*-urocanic acid, can be understood in terms of the competing hydrogen-bonding arrangements and the fact that the more rigid *cis*-urocanic acid side chain will be better disposed for hydrogen bonding than the side chain of histidine from entropic considerations. That this entropic effect is likely to be important is shown by the fact that the pH dependences of the ^{15}N resonances of the imidazole nitrogens of the saturated analog of *cis*-urocanic acid, 3-(4-imidazolyl)propionic acid, are much more similar to those of *trans*-urocanic acid than to the *cis* isomer.³¹

These examples should show the power of ^{15}N NMR to elucidate structural features in solution that cannot be easily obtained in any other way.

1 INTRODUCTION

The structure and dynamics of oxygen-containing compounds is a subject of widespread significance. Compared with ^1H , ^{13}C , ^{31}P , and ^{19}F NMR, however, ^{17}O NMR has received little attention.^{1–8} This neglect is not surprising since, of the naturally occurring oxygen isotopes, only ^{17}O possesses a nuclear spin ($I = \frac{5}{2}$). Due to its electric quadrupole moment ($Q_e = -2.6 \times 10^{-30} \text{ e m}^2$), its low natural abundance (0.037%), and the extremely low absolute sensitivity compared with that of ^1H (about 1.1×10^{-5}), the ^{17}O isotope is one of the more difficult nuclei to observe by NMR spectroscopy. It is, however, of great interest to use a nucleus such as oxygen that is located at strategic molecular sites and is directly involved in inter- and intramolecular interactions. The ^{17}O NMR parameters, i.e. isotropic shielding, principal elements of the ^{17}O shielding and electric field gradient tensors, and the transverse and longitudinal relaxation times, can be considered as excellent means of probing the structure, bonding, and dynamics of oxygen-containing compounds. Furthermore, recent advances in instrumentation, the extremely large chemical shift scale (which aids in the resolution of quadrupole broadened resonances), and the availability of ^{17}O enriched compounds have alleviated these difficulties; thus, an increased use of the ^{17}O NMR technique can be envisaged.^{9–11}

2 EXPERIMENTAL ASPECTS

2.1 The Case of ^{17}O Enrichment

The stringent requirements in studies of compounds at natural abundance are the high concentrations ($>0.1 \text{ M}$) and extensive signal averaging needed.¹² Recording of spectra can be greatly facilitated by the use of ^{17}O enriched samples (Figure 1). When using FT high field instruments and ^{17}O labeled compounds (^{17}O enrichment 10–40 atom %), concentrations of greater than 1 mM are desirable, depending on the linewidths. Synthesis involving oxygen isotopes tends to involve rather straightforward organic reactions. However, one caveat that should be kept in mind when contemplating the synthesis of an ^{17}O labeled compound is the expense

Figure 1 ^{17}O NMR spectra (48.8 MHz; 40°C) of N -[^{17}O]acetyl-L-proline.¹³ (a) 10% enrichment, 0.1 M in aqueous solution containing 1 M NaCl and $5 \times 10^{-5} \text{ M}$ EDTA; $T_{\text{acq}} = 12 \text{ ms}$, NS = 300 000, total experimental time = 1 h: (upper trace) normal spectrum; (lower trace) after a Gaussian-exponential resolution enhancement. (b) 1% enrichment, 0.1 M in methanol, $T_{\text{acq}} = 10 \text{ ms}$, NS = 200 000, total experimental time = 32 min, line broadening (LB) = 50 Hz. (c) 0.4 M natural abundance in acetone (the asterisk marks the carboxyl oxygen resonance); $T_{\text{acq}} = 5 \text{ ms}$, number of scans (NS) = 1 900 000, total experimental time $\approx 10 \text{ h}$, LB = 50 Hz; (d) 1% enrichment, 0.1 M in acetone; $T_{\text{acq}} = 10 \text{ ms}$, NS = 1 350 000, total experimental time $\approx 8 \text{ h}$, LB = 50 Hz. (Adapted by permission of The American Chemical Society from R. N. Hunston, I. P. Gerothanassis, and J. Lauterwein, *J. Am. Chem. Soc.*, 1985, **107**, 2654)

of the starting reagents. Simple modifications of existing reactions are required. For example, $^{17}\text{O}_2$, C^{17}O , or C^{17}O_2 , is added to evacuated systems, as opposed to more traditional procedures which involve bubbling through the reaction mixture. Recently, a comprehensive overview of ^{17}O enriched methods has been published.¹⁴

2.2 Referencing Techniques

As with many heteronuclei, a variety of reference compounds and referencing procedures (both internal and external) have been suggested for ^{17}O NMR. For diamagnetic solutions, an external standard in a combined use of two cylindrical cells has been recommended.¹⁵ Using this technique, doubly distilled water or 1,4-dioxane can be used as external reference. Both compounds have chemical shifts which are indistinguishable at 30–40 °C and their magnetic susceptibility correction is small (<0.6 ppm) relative to common organic solvents. However, H_2O has the disadvantage that its chemical shift varies with temperature (–3 ppm between 27 and 90 °C) due to cleavage of intermolecular hydrogen bonds (the same applies for D_2O in addition to an isotopic effect of –3 ppm).

2.3 Solvent (H_2O) Suppression

Perhaps the most straightforward approach to solvent suppression is the use of ^{17}O depleted water, provided of course that rapid ^{17}O exchange does not occur between solvent and solute.¹⁶ Further suppression can be achieved by exploiting the special relaxation properties of the solvent, by postexperiment data processing and by selectively exciting the whole spectrum apart from that of the solvent.¹⁷ A critical note on the usefulness of the selective excitation pulse sequences in ^{17}O NMR has recently been published.¹⁸

2.4 Acoustic Ringing

Observation of very broad resonances in NMR is a potential problem due to baseline distortions. The most severe of the baseline artifacts is that due to the transient response of the NMR probe, often referred to as ‘acoustic ringing’, caused by the generation of ultrasonic waves from the action of the rf pulse. In the last decade, several pulse sequences designed for the suppression of acoustic ringing have been reported, and the reader should consult a relevant review article for details.¹⁹ For experiments in solution, the extended spin echo sequence was found to be particularly useful, since it utilizes minimum pulse and preacquisition delay times. A closely related pulse sequence for experiments in the solid phase has also been suggested.²⁰

3 CHARACTERISTIC PARAMETERS

3.1 Chemical Shifts

3.1.1 Experimental Shielding Ranges: Empirical Correlations

A general pattern of ^{17}O shielding is shown in Figure 2. For compounds containing oxygen bonded only to carbon and/or hydrogen there is a clear correlation between the C–O π bond order and a high frequency shift.²¹ This type of correlation arises from the multiple bond term $\Sigma_{B \neq A} Q_{AB}$ in the Karplus–Pople equation.²² For bridging oxygen atoms, a strong deshielding is observed when the substituents R are replaced by π -accepting acyl substituents which introduce π

Figure 2 ^{17}O chemical shift ranges for different X–O bonds. (Adapted by permission of Plenum Press from W. McFarlane and H. C. E. McFarlane, in ‘Multinuclear NMR’, ed. J. Mason, 1987, Chap. 14)

character into the C–O bond of the bridging oxygen. Thus, bridging oxygen resonances in carbonates and esters appear at high frequency relative to the corresponding resonances in alcohols, ethers, and acetals. An even greater high frequency shift is observed for anhydrides, where bridging oxygen atoms are bonded to two π acceptors. If chemical shifts are assumed to depend linearly on π bond order, the chemical shift of about 600 ppm for aliphatic aldehydes (π bond order of about 1) relative to water (π bond of 0) implies a chemical shift of about 200 ppm for CO_3^{2-} (π bond order of $\frac{1}{3}$). The observed shift of CO_3^{2-} (192 ppm) is in agreement with this crude prediction, further supporting the general correlation between π bond order and shielding discussed above.²

In nitrogen-containing compounds, as in carbon compounds, chemical shift values are determined largely by π bonding effects.^{23–25} Bridging oxygen resonances are observed at even higher frequency in nitrates, where π bonding is appreciable. A lesser, but nonetheless significant, effect is observed for bridging oxygen atoms in nitrates. The most striking feature of the ^{17}O shifts observed for P–O bonds is the small chemical shift range (20–260 ppm) which cannot be related to P–O bond order in a straightforward fashion. However, ^{17}O resonances for nonequivalent oxygen atoms in phosphates and polyphosphates can be resolved and have been used in stereochemical and binding site studies.^{26–28} For S–O bonding, similar trends to those displayed by P–O bonds are observed. Modification of the π bond order in an X=O group due to substituents on X results in a decrease (or increase) in the net charge on X as the charge on oxygen increases (or decreases). The chemical shift variations experienced by the nuclei X and O are then opposite and roughly proportional to the ratio $\langle r^{-3} \rangle_{2\text{px}} / \langle r^{-3} \rangle_{2\text{pO}}$.²⁴ For a series of oxyanions and a series of C=O and N=O compounds a linear correlation has been found between $\delta(^{17}\text{O})$ and the variation in ΔE^{-1} .²⁹ A linear correlation exists between acetone chemical shifts and the first maximum of the $n \rightarrow \pi^*$ transition for acetone/water

solutions³⁰ and for acetone in different solvents.³¹ Similar trends have also been observed in a variety of substituted acetophenones;³² however, it was suggested that such trends may be fortuitous, since the transition energy depends upon the balance of several effects associated with both π donation and σ withdrawal.³³ From a study on a series of aliphatic ethers, a correlation between $\delta(^{17}\text{O})$ and the first ionization potential has been suggested.³⁴

Compounds containing oxygen–oxygen bonds and oxygen–fluorine bonds display large high-frequency shifts.^{35–37} The ability, therefore, of ^{17}O NMR to distinguish unambiguously between nonequivalent oxygen atoms has found application in several structural and mechanistic studies. The same applies to oxygen bonded to transition metals (see below). Empirical correlations were extended to diamagnetic transition metal anions of the general formula MO_4^{n-} , and theoretical calculations were carried out to show that the absolute magnitude was reasonable.²⁹

3.1.2 Theory of ^{17}O Chemical Shifts (see *Shielding: Overview of Theoretical Methods*)

3.1.2.1 Isolated Molecules. Ab initio calculations^{38,39} of ^{17}O nuclear shielding tensors have been reported for a variety of simple molecules such as H_2O , CH_3OH , $(\text{CH}_3)_2\text{O}$, H_2CO , CH_3CHO , HCONH_2 , and CO . The results are gauge dependent and in many cases vary considerably depending on the basis set used. Gauge independent ab initio results for H_2O and H_2CO indicate a ^{17}O shielding of 757.6, 860.3, or 858.8 ppm for H_2CO , with respect to H_2O , compared with the experimental result of 580–600 ppm. The calculated data represent a choice of three basis sets. Semiempirical INDO (intermediate neglect of differential overlap) calculations are numerically smaller than the experimental results, whereas the CNDO/S (complete neglect of differential overlap/S) calculations produce better overall agreement.^{40–43} This probably reflects an insensitivity of the INDO orbital energies to changes in the environment of the oxygen. By omitting those molecules and ions which have nitrogen directly bonded to oxygen the CNDO/S results gave a standard deviation of 30.6 ppm and a correlation coefficient of 0.98 compared with the experimental values. Analysis of the CNDO/S results demonstrates that the ^{17}O shielding differences of some carbonyl compounds are dominated by the lowest energy $n \rightarrow \pi^*$ transition. For the linear species CO , CO_2 , and NO_2^+ , the largest contribution to the paramagnetic part σ_p of the ^{17}O shieldings arises from the lowest energy $\sigma \rightarrow \pi^*$ transition. Similarly, for the bent ion NO_2^- the lowest energy $\sigma \rightarrow \pi^*$ transitions are dominant for the in-plane components of the shielding tensor, while the out-of-plane contribution is controlled by $\sigma \rightarrow \sigma^*$ transitions. In general, these ^{17}O shieldings are in reasonable agreement with the available experimental data, and in some cases are an improvement upon ab initio results. Analogous calculations employing a basis set of gauge dependent atomic orbitals within the CNDO/2 framework have been reported for ^{17}O shieldings in electrolyte solutions.⁴⁴ For ozone,⁴⁵ the use of localized molecular orbitals within the IGLO method (see *Shielding Calculations: IGLO Method*) allows the contributions to the total shielding to be partitioned into orbital contributions, so that the specific role played by the lone pairs on the atom in question and orbitals centered on neighboring atoms can be discerned.⁴⁶ The calculated shieldings for O_3

were found to be extremely large, highly anisotropic, and to differ from the experimental values by a factor of 2–3. The authors also noted that the paramagnetic contributions are mainly due to the lone pairs on the respective oxygen atoms, unlike the triatomic molecules CO_2 and FNO in which the paramagnetic contributions are mainly due to the bonds interacting with the antibonding π^* electrons and only to a limited extent to the lone pairs.

3.1.2.2 Solvent and medium effects. Recently, the effect of electrical polarization on the chemical shielding of carbon monoxide has been considered in detail.^{47,48} In addition, the relationship between the vibrational frequency and the shieldings for three different types of electrical environments—a uniform field, a field gradient, and an axial point-charge dipole—together with experimental ^{13}C and ^{17}O isotropic shieldings and vibrational frequencies for a range of carbon monoxide derivatives of heme proteins has been described. For each type of environment, the shieldings vary linearly with the vibrational frequency for a relatively wide range of frequency shifts.⁴⁸ This shows, in agreement with experiment,⁴⁹ that there is a linear relationship that is opposite for ^{13}C and ^{17}O .⁵⁰

The effects of solvents on the ^{17}O nuclear shielding of solute molecules may be categorized into hydrogen-bonding interactions and influences that arise from electronic interactions between the dipole moments of the solute and solvent molecules. Precise mathematical expressions are not available for many nonbonded interactions. Consequently, continuum models tend to be more popular for investigating solvent effects on NMR parameters. The most widely used of these, to date, is the solvaton model.⁵¹ By means of this model the solute–solvent interaction can be included in the paramagnetic screening contribution, and the solvent induced shift is proportional to $(\epsilon - 1)/2\epsilon$, where ϵ is the dielectric constant of the medium. Some sum-over-states (SOS) and finite perturbation theory (FPT) calculations of oxygen nuclear shieldings of several organic functional groups, as obtained using the solvaton model, predict increases in shielding as ϵ increases.^{50,52} An analysis of the various factors contributing to the paramagnetic term reveals that the increase in shielding arises from a concomitant decrease in $\langle r^{-3} \rangle_{2p}$ and an increase in the weighted average of the energies of the various transitions contributing to the paramagnetic term. The observed decrease in $\langle r^{-3} \rangle_{2p}$ is consistent with an increase in the average separation between the nucleus and its 2p electrons as the charge q increases. The increase in the weighted averaged of the transition energies is largely controlled by the increase in energy of the lowest $n \rightarrow \pi^*$ transition as the extent of solvation increases.

The shielding of the ^{17}O nuclei of several functional groups are quite sensitive to hydrogen-bonding interactions. From a theoretical standpoint the shielding may be considered by using the supermolecule approach. A good example is provided by formamide.⁵³ Ab initio calculations using GIAOs (gauge invariant atomic orbitals) within the FPT framework have been reported for formamide (FMA) in the presence of its first hydration shell. The ^{17}O shielding values reported for the complexes $\text{FMA}-(\text{H}_2\text{O})_2$ show that the shift observed when the oxygen atom is directly involved in the hydrogen bond is much larger than the one occurring when the water molecules are bound to the NH group. The variation was calculated to be to low frequency in both cases. This is in agreement with

^{17}O NMR experimental data on FMA and several amides in different solvents.

3.2 Indirect Spin Coupling Constants

Because of the breadth of ^{17}O resonances, only relatively large coupling constants can be measured, and hence the majority of those recorded refer to couplings from directly bonded nuclei. $^1J(\text{O,H})$ in water and alcohols has values close to 80 Hz.^{54–56} The $^1J(\text{P,O})$ couplings involving P=O groups cover a fairly wide range (145–210 Hz) and for a series of compounds of type OPX_3 ($\text{X} = \text{F}$ or O in OMe , $\text{X} = \text{N}$ in NMe_2 , and $\text{X} = \text{C}$ in Me) there is a consistent drop in coupling with decreasing electronegativity of X . This may be qualitatively attributed to the electronegative substituents removing electrons in outer orbitals from the phosphorus atom, leading to a greater effective atomic charge and hence stronger contact interaction between the phosphorus nucleus and the s orbitals. A finite perturbation theoretical treatment within the CNDO/2 formalism has reproduced the observed trends, but not the absolute values.⁵⁷ The oxygen atoms in P-OMe groups within phosphates give rise to a consistently smaller coupling constant, compared with P=O , of between 90 and 100 Hz; there is an indication of a considerably larger value for phosphites. The reduced coupling constants decrease with increasing atomic number of the central atoms along the isoelectronic sequence VO_4^{3-} , CrO_4^{2-} , and MnO_4^- .⁵⁸ The values of ^{17}O spin–spin couplings have been used to investigate H_3O^+ species.⁵⁹ The ^{17}O NMR spectrum revealed a perfect quartet with $J(\text{O,H}) = 107$ Hz. Furthermore, the effect of H/D substitution is evident in the ^{17}O NMR spectra of $\text{H}_2\text{O-D}_2\text{O}$ in CH_2Cl_2 . Thus, the species H_2O , HDO , and D_2O could be identified from coupling constants, without reference to chemical shift data.⁶⁰ 2J couplings are normally about an order of magnitude smaller than the corresponding directly bonded couplings.⁶¹ However, there seems to be a particularly favored coupling pathway from hydrogen to the ‘ether’ oxygen atom in HCOOR systems, which is probably associated with π bonding across the planar framework.

In some cases coupled resonances cannot be resolved into fine structure but exhibit a partially collapsed structure, depending on the rate of proton transfer. In such cases decoupling of the other nuclei can lead to reduced linewidths and information about coupling constants.

When a spin- $\frac{1}{2}$ nucleus is bonded directly to ^{17}O , the X nucleus will also be relaxed by virtue of its spin–spin coupling with ^{17}O . This has been termed ‘scalar relaxation of the second kind’. Such a line-broadening effect for ^{17}O in ^{31}P NMR has been used to locate the position of the ^{17}O label and to calculate the percentage enrichment of ^{17}O . In addition, it has made possible analysis of the configuration of (^{16}O , ^{17}O , and ^{18}O) phosphate monoesters and (^{16}O , ^{17}O , and ^{18}O) thiophosphates by ^{31}P NMR.^{62–64}

3.3 Nuclear Quadrupole Coupling Constants

The electrostatic interaction between the nuclear quadrupole electric moment Qe and the electric field gradient tensor eq_{ij} is the quadrupolar interaction. An appropriate reference axis system can be chosen to reduce this interaction to two values:⁴ the main component

$$\chi = e^2 q_{zz} Q / h \quad (1)$$

and the asymmetry parameter (dimensionless)

$$\eta = (e^2 q_{xx} Q - e^2 q_{yy} Q) / e^2 q_{zz} Q \quad (2)$$

where $|e^2 q_{zz} Q| > |e^2 q_{yy} Q| > |e^2 q_{xx} Q|$.

The χ values for ^{17}O may be calculated by computing the field gradient from molecular wavefunctions and using the nuclear quadrupole moment Qe . Only relatively small molecules have been studied. Thus the calculated χ value for CO using the GAUSSIAN 88 program at the 6-31G* level⁴⁹ (3.1 MHz) was found to deviate from the experimental value (~ 4.4 MHz) (the value of 3.9 MHz obtained from ab initio calculations⁴⁷ is in better agreement with the experimental value). Furthermore, it was shown that hydrogen bonding to HF results in a significant decrease in χ of about 0.7 MHz for the linear species $\text{CO} \cdots \text{HF}$.

Semiempirical methods of various degrees of sophistication have been used to compute electric field gradients. Within the framework of the Townes–Dailey theory, the three components of the field gradient can be related to the electronic populations in the orbitals describing the oxygen bonding and to eq , the field gradient created by an electron in a $2p$ atomic orbital (the contribution from the valence s electrons is neglected because of the spherical symmetry). More elaborate models incorporate hybridization of atomic orbitals into valence bonding and lone pair orbitals. Such studies include the determination of σ and π orbital populations for X-O bonds ($\text{X} = \text{C}, \text{N}, \text{P}, \text{or } \text{S}$).^{65,66}

The majority of experimentally determined χ and η values have been obtained in the solid state by the use of NQR spectroscopy; however, some have been determined by NMR measurements on powders or single crystals, where χ is small with respect to the NMR frequency. Quadrupole coupling constants have also been derived from the splittings in the ^{17}O spectra of molecules partially oriented in an electric field⁶⁷ or dissolved in a nematic liquid crystal.^{68,69} Detailed studies of polynuclear osmium carbonyl dynamics have been undertaken and together with ^{13}C measurements have provided estimates of the ^{17}O quadrupole coupling constants.⁷⁰ In molybdenum hexacarbonyl, the ^{95}Mo and ^{97}Mo linewidths gave the reorientational correlation time, which in turn made it possible to determine the χ values from the ^{17}O linewidth.⁷¹

Experimental χ values cover the range -8 to 17 MHz. The sign of χ is irrelevant to the NMR experiment, but from a theoretical point of view it gives information about the orientation of the field gradient. The experimental χ values for a series of compounds in the solid state that contain C=O , -O- , P-O , N-O , or S-O bonds show the following trends:⁶

1. For substituted nitrophenols, hydroxybenzaldehydes, and nitrobenzaldehydes, the χ values are nearly invariant with the electronic properties of the substituent, but are reduced by hydrogen bonding.
2. Strong hydrogen bonding reduces the χ values by as much as 2.6 MHz.

In summary, the following scale of χ values has been suggested:

The ^{17}O χ values for the terminal CO groups in metallocarbonyls were found to be 1–3 MHz, although values below 0.1 MHz have also been observed. It was suggested that increased $d\pi - p\pi$ back-bonding from the metal will increase electron density perpendicular to the C–O axis and so reduce the χ values.⁷²

3.4 Relaxation Properties (see *Relaxation Theory for Quadrupolar Nuclei*)

3.4.1 Relaxation in the Extreme Narrowing Condition

In isotropic systems and in the absence of chemical exchange, the T_1 and T_2 relaxation times are equal and are given by

$$1/T_1 = 1/T_2 = 3/125(1 + \eta^2/3)\chi^2 f(\omega, D) \quad (3)$$

where χ is the nuclear quadrupole coupling constant. The asymmetry parameter η varies from 0 to 1 and describes the deviation of the electric field gradient from axial symmetry. $f(\omega, D)$ is the correlation function, which depends on the rotational diffusion constant D and its relative orientation with respect to the principal axes of the field gradient tensor. When isotropic reorientation is assumed, $f(\omega, D)$ reduces to the single correlation time τ_c . If the resonance absorption is a Lorentzian lineshape, the linewidth at halfheight $\Delta\nu_{1/2}$ is a direct measure of the relaxation time, provided that unresolved indirect spin coupling is not present and that chemical exchange phenomena do not take place. From equation (3) it is clear that the product $\chi^2(1 + \eta^2/3)$ can be obtained from ^{17}O relaxation times if the correlation time governing the relaxation is known. The Debye formula allows only the determination of the correct order of magnitude of τ_c . More precise values of τ_c could be obtained from the relaxation of other nuclei, such as ^{13}C or other quadrupolar nuclei; however, one should be aware of possible anisotropic reorientations due to molecular tumbling.⁴

3.4.2 Relaxation Outside the Extreme Narrowing Condition

In this case, the decay of the longitudinal (M_1) and transverse (M_2) magnetizations is no longer exponential but may be written as a weighted sum of $I + \frac{1}{2}$ exponentials:⁷³

$$M_1(t) = M_1(\infty) \left\{ 1 - k \left[\sum_{i=1}^{I+1/2} C_{1,i} \exp(-R_{1,i}t) \right] \right\} \quad (4)$$

$$M_2(t) = M_2(0) \left[\sum_{i=1}^{I+1/2} C_{2,i} \exp(-R_{2,i}t) \right] \quad (5)$$

Figure 3 Longitudinal (a) and transverse (b) relaxation of spin- $\frac{5}{2}$ nuclei in the absence of chemical exchange. The upper plots show the normalized amplitudes $C_{1,i}$ and $C_{2,i}$ of the three exponential components as a function of $\omega_0 \tau_c$ (coefficients 2 and 3 are plotted on the expanded scale given to the right). The lower plots show the relaxation rates as a function of the same parameter. (Adapted by permission of The American Institute of Physics from T. E. Bull, S. Forsen, and D. L. Turner, *J. Chem. Phys.*, 1979, **70**, 3106)

where $\sum_{i=1}^{I+1/2} C_{j,i}$ and $k = 2$ for an inversion–recovery experiment. Furthermore, although equation (4) is valid for the total magnetization, the decays of the individual components will normally not be exponential and will also depend on the length of the monitoring pulse. Equations (4) and (5) cannot be solved analytically, but must be solved numerically for each value of $\omega_0^2 \tau_c^2$. Figure 3 illustrates the longitudinal and transverse relaxation of spin $I = \frac{5}{2}$ nuclei in the absence of chemical exchange. The longitudinal relaxation may be regarded as a single exponential, within the limits of experimental error, for all correlation times. Conversely, the transverse relaxation is governed by the three contributions and the weights of the different contributions have similar magnitudes for the longer correlation times. For values of $\omega_0^2 \tau_c^2 \ll 1$, the transverse relaxation is approximately a single exponential. In the slow motion limit the rapid decay of the third component at longer correlation times may allow analysis in terms of just two exponential terms.

In addition to nonexponential relaxation for quadrupolar nuclei under conditions of nonextreme narrowing, the NMR signal will also be modified by shift changes which have been termed ‘second-order dynamic frequency shifts’ (see *Quadrupolar Interactions and Dynamic Frequency Shift*). Although long recognized theoretically, the experimental demonstration of such a phenomenon is not straightforward, since the symmetry of the composite peak is in practice difficult to distinguish from small phase misadjustment and is thus usually overlooked. Furthermore, strongly relaxed transitions may decay so quickly as to be undetected if the instrument deadtime is too long. Expressions for the NMR bands for $I = \frac{5}{2}$ and $I = \frac{7}{2}$ nuclei have been derived, both in the presence and the absence of chemical exchange.⁷⁴ In the limit $\omega_0 \tau_c \gg 1$, the $m = \frac{1}{2} \rightarrow m = -\frac{1}{2}$ component will dominate the spectrum because it is much narrower than the other components. This narrow signal will be shifted

towards lower frequency with a value proportional to χ^2/ω_0 . Between these two limits the resonance will be more or less asymmetric, with an apparent shift to either high or low frequency depending on the values of ω_0 , τ_c , and χ . The ratio of the dynamic shift to the linewidth $\Delta\omega_d/\Delta\omega_{\frac{1}{2}}$ in this region depends only on ω_0 and τ_c .

3.4.3 Effects of Relaxation Mechanisms Other Than Quadrupolar

It is evident from Figure 3 that the linewidth of the narrow component decreases as τ_c increases in the slow motion limit, while the linewidths of the intermediate and broad components increase. However, the linewidth of the narrow component does not necessarily decrease as τ_c increases if the chemical shift anisotropy is large. Such behavior has been observed in studies of the temperature and magnetic field strength dependence of ^{17}O NMR spectra of myoglobin MbC ^{17}O samples.⁷⁵ For $\tau_c \simeq 14$ ns and $\sigma_{\parallel} - \sigma_{\perp} = 800$ ppm (which is the value for a model heme compound obtained from NMR studies in the solid state) a CSA contribution to the linewidth of about 100 Hz was obtained for the narrow components. This value is comparable to that of the pure quadrupolar contribution to the linewidth (about 96 Hz). The CSA contribution to T_1 was found to be negligible (about 170 ms).

4 SELECTED APPLICATIONS

4.1 Dynamic and Kinetic Studies

Numerous dynamic and kinetic studies have been performed using ^{17}O NMR. Lineshape analysis is not straightforward because the linewidth itself is temperature dependent. Nevertheless, it has been shown that dynamic ^{17}O NMR is a convenient alternative to ^{13}C NMR for studies of metal carbonyl compounds.⁷⁶ A solution of $\text{HFeCO}_3(\text{CO})_{12}$ at -89°C gives only two ^{13}CO signals in a ratio of 1:2 instead of the expected four signals with a 1:1:1:1 ratio. In ^{17}O NMR, the four signals are easily observed at -11°C and a two-step exchange process averages all the sites, producing a single line at 108°C .

^{17}O NMR has been used to measure the rate of oxygen exchange in aldehydes and ketones,⁷⁷ cobaloximes,⁷⁸ and the periodate–water system.⁷⁹ It is possible to measure either the decay of a signal from a group enriched in ^{17}O or the growth of a signal that is undergoing exchange with ^{17}O labeled water.³

A substantial number of publications has been concerned primarily with studies of the hydration of ions in solution. The ^{17}O chemical shift of water molecules bound to Al^{3+} was found to be about 11 ppm to high frequency. Temperature dependence studies and lineshape analysis yielded the ^{17}O nuclear relaxation rates of the bound and free water molecules, the coordination number, and the rates of exchange between the bound and free water.⁸⁰ In addition, the thermodynamic parameters for activation characterizing the exchange reaction can be obtained. In cases where the chemical shift between ‘bound’ and ‘free’ water molecules is small, leading to overlapping of resonances, the resonance of the ‘free’ molecule can be shifted by adding small amounts of a paramagnetic salt.

Estimates of 4, 6, and 6 for the hydration numbers of $\text{Be}(\text{II})$, $\text{Al}(\text{III})$, and $\text{Ga}(\text{III})$ were obtained from area measurements. An alternative method of determining hydration numbers, by evaluating the magnitude of the shift of the water resonances caused by the dissolved paramagnetic ion, has also been suggested.⁸⁰

There is an extensive literature on ^{17}O NMR studies of the exchange rates of water molecules bound to paramagnetic ions.^{81–84} In this case there is a much greater chance of observing separate resonances from ^{17}O nuclei in ‘bound’ water molecules in the solvation shells of paramagnetic cations than in the corresponding diamagnetic cations. The magnitudes and temperature dependences of the linewidths (or relaxation time measurements) of the ‘bound’ and ‘free’ resonances, and the chemical shift separations between these resonances, can in principle be used to derive information about the hyperfine splitting constant, a_N , the rate of the solvent interchange process, T_e , and the solvation number. However, because the shifted resonance of the solvated water molecules is also often very broad, it is rarely possible in practice to derive the hydration number of the paramagnetic cation from straightforward area measurements. In such cases the hydration numbers may be obtained by using the theory developed by Swift and Connick⁸⁵ who investigated a variety of systems. This type of work and the chemical significance of the results have been reviewed (see *Paramagnetic Relaxation in Solution*).⁸⁶

4.2 ^{17}O NMR and Torsion Angle Effects

^{17}O NMR spectroscopy is a powerful method for detecting steric effects in molecules in which the steric interactions are characterized by the rotation of functional groups about single bonds to relieve van der Waals interactions or in rigid systems in which the steric interactions are partially accommodated by bond angle and bond length distortions.⁸⁷ ^{17}O deshielding is expected when the rotation leads to greater double bond character or reduced electron density on oxygen (e.g. in an isolated carbonyl group). Shielding, however, is observed in the situation in which the carbonyl group assumes more single bond character or increased density on the oxygen atom. Studies of such steric effects have been done on aromatic and heteroaromatic nitro compounds, aryl ketones, aldehydes and 1,2-diketones, aromatic carboxylic acids, esters and amides.^{88–91} For nitro aromatic compounds, a quantitative relationship was established between $\delta(^{17}\text{O})$ of the nitro group and the torsional angle between the aromatic ring and the nitro group (Figure 4). It appears that the solid state conformational preference, and thus the angle, is in remarkably good agreement with the average angle determined in the solution state.

4.3 Hydrogen-Bonding Effects (see *Hydrogen Bonding*)

The use of ^{17}O NMR appears to be especially promising for studying hydrogen-bonding interactions, because of the large chemical shift range of the oxygen nucleus.^{92–94} The dominance of intramolecular hydrogen-bonding effects over substituent effects has been clearly demonstrated in acetophenones, benzaldehydes, and hydroxynaphthoquinones.^{32,95} In

Figure 4 Plot of the torsion angles (X-ray) between aromatic rings and nitro groups versus ^{17}O chemical shift data.⁸⁷ (Reproduced by permission of CRC Press, Inc., from D. W. Boykin and A. L. Baumstark, in ' ^{17}O NMR Spectroscopy in Organic Chemistry', ed. D. W. Boykin, 1991, Chap. 3)

amides and peptides,^{10,93,96–100} both long-range dipole–dipole interactions and specific hydrogen bonds at the amide oxygen atom induce significant and specific shielding of the ^{17}O nucleus. Thus the overall chemical shift change between an amide oxygen atom in the absence of hydrogen-bonding interactions in vacuum and one that is fully hydrated in aqueous solution is, very probably, over 95 ppm. There is a linear correlation between $\delta(^{17}\text{O})$ and $\nu(\text{CO})$, the infrared (IR) amide I stretching vibration, for different solvents which have varying dielectric constants and solvation abilities.¹⁰⁰ This demonstrates that both IR and ^{17}O NMR spectroscopy appear to be reflecting a similar type of electronic perturbation, i.e. hydrogen bonding and dipole–dipole solute–solvent interactions. Further studies include investigations of the hydration and intra- and intermolecular hydrogen bonding of the *cis/trans* peptide oxygen atoms in AcYOH and AcYNHMe (Y = Pro or Sar)^{13,98} (Figure 1), protected dipeptides,⁹⁹ and peptide hormones.^{101–103}

4.4 Oxygen Bonded to Transition Elements (Polyoxometalates)

^{17}O NMR has been employed frequently in stereochemical studies of polynuclear, anionic oxo complexes (polyoxoanions) of the early transition elements in a variety of oxidation states.^{104–108} In spite of their structural complexity, these polyoxoanions often yield well resolved ^{17}O NMR spectra, since large chemical shifts are observed and samples may often be observed at elevated temperatures in nonviscous solvents. Furthermore, ^{17}O enrichment is easily obtained. A representative example is the $[\text{V}_{10}\text{O}_{28}]^{6-}$ species, the structure and spectrum of which are shown in Figure 5. Exchange of oxygen atoms in the complex ion with those of H_2^{17}O in aqueous solution showed that all the different oxygen sites could be identified separately by their shieldings. If an oxygen atom attached to n vanadium atoms is designated as OV_n , then the observed chemical shifts are: $\text{OV} \simeq 1150$; OV_2 (three different sites) $\simeq 900, 790$ and 760 ; $\text{OV}_3 \simeq 390$; and $\text{OV}_4 \simeq 65$ ppm. It can be seen that there is a systematic reduction in $\delta(^{17}\text{O})$ with an increase in the number of vanadium atoms to which the oxygen atom is bound. Other complex anions of the formula $[\text{M}_6\text{O}_{19}]^{n-}$, where M = Mo ($n = 2$), Nb

Figure 5 (a) The D_{2h} symmetrized structure of $\text{V}_{10}\text{O}_{28}^{6-}$. Small filled circles represent vanadium atoms and large open circles represent oxygen atoms. One member of each symmetry-equivalent set of atoms is labeled. (b–e) ^{17}O NMR spectra at 13.5 MHz of $\text{V}_{10}\text{O}_{28}^{6-}$ in H_2O . All spectra were measured at 25°C with total vanadium concentrations of 1.5–1.8 M. The asterisk labels the metavanadate resonance. (Adapted by permission of The American Chemical Society from W. G. Klemperer and W. Shum, *J. Am. Chem. Soc.*, 1977, **99**, 3544)

($n = 8$), or Ta ($n = 8$), show the same qualitative regularities in shielding, with $\text{OM} > \text{OM}_2 > \text{OM}_6$. These regularities have been interpreted as a correlation between increasing chemical shift and increasing π bonding from the metal to the oxygen in different sites. The regularities persist in the ^{17}O spectra of a variety of more complex anions of lower symmetry in which other metals or nonmetals are substituted within an $[\text{M}_x\text{O}_y]^{n-}$ framework. It should be noted that the resonances of oxygen nuclei in the highly symmetrical environments of the complex anions, e.g. OM_4 or OM_6 , are relatively sharp. This is to be expected because the field gradient at these positions will be zero or very small; hence the normally dominant quadrupolar relaxation mechanism will be very weak and the relaxation times correspondingly long.

4.5 Heme Proteins and Model Compounds—Substrate Binding to Enzymes

The ^{17}O NMR spectra of several heme model compounds in solution have been reported.^{11,109–111} Two signals at about

Figure 6 ^{17}O NMR spectra (54.2 MHz) of the oxygenated compounds **a** (---) and **b** (—) with a preacquisition delay time $\Delta t = 50 \mu s$ and recorded in two steps with the carrier frequency on the absorption resonances. Maximum concentration $\approx 10^{-2} M$ in toluene solution. Concentration of 1,2-dimethylimidazole (1,2-Me₂Im) $\approx 5 \cdot 10^{-1} M$, $T = 297 K$, NS = 1 080 000 (LB = 1 kHz) and 350 000 (LB = 500 Hz) for the high- and low-frequency resonances, respectively. The arrow denotes the region of the resonance position of the terminal oxygen atom of the picket-fence porphyrin model, with excess 1-MeIm, and ether models in which no hydrogen bonding interactions are expected. (Adapted by permission of the Royal Society of Chemistry from I. P. Gerothanassis, B. Look, and M. Momenteau, *J. Chem. Soc., Chem. Commun.*, 1992, 598)

1750 and 2500 ppm were observed for the FeO₂ linkage (Figure 6). The data were interpreted as ruling out sideways triangular bonding in favor of an end-on angular bonding arrangement. The data were explained in terms of bonding models in which the electrons of the FeO₂ moiety are totally paired.

Analysis of the ^{17}O relaxation and chemical shift data of $C^{17}O$ ligated hemoproteins has provided information on both the structural and the dynamic properties of the heme group.^{49,75,112} Peroxidases are heme proteins with molecular weights of about 40–42 kDa that catalyze oxidations by hydrogen peroxide. They contain iron-protoporphyrin IX as a noncovalently bound prosthetic group. The ^{17}O NMR spectra of CO-horseradish peroxidase isoenzyme C (Figure 7) indicate a single hemoprotein $C^{17}O$ signal (at 358.3 ppm) below pH 10 and two separate signals at pH 10.5. The new signal, which was assigned with the alkaline form of CO-horseradish peroxidase isozyme C, is broader and at about 7 ppm to high frequency relative to that of the acidic form. A similar pH-dependent relationship of the chemical shift and linewidth was observed for CO-horseradish peroxidase isozyme A and CO-horseradish peroxidase isozyme C. It was concluded that CO-horseradish peroxidase isozyme C undergoes a transition between the acidic and alkaline forms.¹¹² However, unlike the case of CO-horseradish peroxidase isozyme A, the transition is slow on the NMR timescale (see *Oxygen-17 NMR: Applications in Biochemistry*).

4.6 Hydration of Proteins: Water Orientation in Lyotropic Phases and Bilayers

Water plays a fundamental role in the conformation and activity of biological macromolecules (see *Protein Hydration*).

Figure 7 Oxygen-17 NMR spectra of CO-horseradish peroxidase isozyme C (CO-HRPC); concentration, 1 mM in 50 mM phosphate buffer at 11.7 T; NS = 50 000–250 000, recycle time 100–150 ms, pulse width $38 \mu s$, LB = 100 Hz. A, B, and CO_{aq} denote the acidic form of CO-HRPC, the alkaline form of CO-HRPC, and free CO in solution, respectively. (Reprinted by permission of The American Society for Biochemistry and Molecular Biology from H. C. Lee, K. Cummings, K. Hall, L. P. Hager, and E. Oldfield, *J. Biol. Chem.*, 1988, **263**, 16 118)

^{17}O NMR studies have several advantages compared with 1H and 2H NMR for protein hydration:

1. The relaxation effect is large, permitting studies at low protein concentrations.
2. The ^{17}O relaxation in water is generally dominated by the quadrupolar mechanism.^{113,114} The intramolecular origin of the electric field gradient makes the quadrupolar interaction virtually independent of the molecular environment.
3. The ^{17}O relaxation is not affected by proton (or deuteron) exchange with protic residues in the protein. Only T_2 can be affected by exchange within a narrow pH range near neutrality.
4. Cross relaxation that contributes to 1H relaxation is unimportant for ^{17}O .^{115,116}

Variable field T_1 and T_2 relaxation time measurements of several proteins¹¹⁷ were interpreted in terms of two layers of

hydration having a reorientational correlation time of about 20 ps (about eight times slower than that of bulk water and independent of the nature of the protein). This rapid local motion has a small anisotropic component (corresponding to an order parameter of 0.06) which is averaged out by protein reorientation with a correlation time of the order of 10 ns.

Water molecules are important constituents of lyotropic phases and bilayers. In this case the molecular motions are strongly anisotropic and the quadrupolar interaction is not averaged out to zero and may be measured when it is small compared with the Zeeman interaction. Ordering of a water molecule results in a quadrupolar splitting which is related to the order parameter. It has been shown that important dynamic information can be obtained from ^{17}O linewidth data which complement the ordering results from ^2H NMR.¹¹⁸ (see *Amphiphilic Liquid Crystalline Samples: Nuclear Spin Relaxation* and *Liquid Crystalline Samples: Structure of Nonrigid Molecules*).

4.7 The Solid State

Under conditions of magic angle spinning (MAS) (see *Magic Angle Spinning*), the $(\frac{1}{2}, -\frac{1}{2})$ transition of quadrupolar nuclei with nonintegral spin does not depend on first-order quadrupolar interactions or on the effects of θ (the angle between B_0 and q_{zz}). The powder bandshapes depend upon second-order quadrupolar effects which do not eliminate the possibility of obtaining meaningful NMR spectra. In this case operation at very high magnetic fields will generally be most advantageous since the maximum second-order quadrupolar linewidth of the $(\frac{1}{2}, -\frac{1}{2})$ transition decreases linearly with the magnetic field.¹¹⁹ Typical results are those obtained for a range of oxides, oxyanions and high temperature oxide superconductors.^{120–122} For fosterite (Mg_2SiO_4), in which three crystallographically distinct oxygen sites were partly resolved, it was possible to determine the chemical shifts (61, 62, and 47 ppm), the quadrupole coupling constants (2.35, 2.35, and 2.7 MHz), and the electric field gradient tensor asymmetry parameters (0.2, 1.0, and 0.3) associated with each. From similar studies of silicate minerals and other compounds it was found that the χ values are related to the percentage ionic character of the bonds to oxygen.¹²⁰ It has also been found that VAS can be advantageous, especially for removing resonances arising from transitions other than $(\frac{1}{2}, -\frac{1}{2})$ (see *Variable Angle Sample Spinning*). Furthermore, it has been demonstrated that ^{17}O spins can be polarized by the ^1H spin system, as is done for ^{13}C in CP MAS.¹²³

^{17}O NMR studies on single crystals have the advantage, compared with studies on powders, that the complete principal components of the nuclear quadrupolar coupling constant and shielding tensors can be obtained and their orientation relative to the local molecular symmetry can be determined.¹²⁴

1 INTRODUCTION

With the discovery of the phenomenon of NMR in bulk samples in 1945, a new, powerful, analytical method became available to chemists. The ^{31}P nucleus was among the first nuclei to which NMR spectroscopy was applied. Phosphorus-31 spectroscopic data have been in the literature since 1951,^{1,2} and their number increased rapidly in the following years. In 1967 the first comprehensive compilation of ^{31}P NMR data of simple phosphorus compounds, as well as a presentation of the current theory of phosphorus chemical shifts, was published.³ Another publication⁴ and a review⁵ cover the literature up to 1969 and to mid-1982, respectively.

With the development of pulse Fourier transform NMR spectroscopy the sensitivity of the spectrometers improved and the ^{31}P NMR experiment became routine. As a consequence the amount of published ^{31}P NMR data increased dramatically. By 1987 it was estimated that more than 40 000 ^{31}P NMR data items were available in the literature. A 'Handbook of ^{31}P NMR Data' contains extensive compilations of representative data, including coupling constants, for all types of phosphorus compounds.⁶ More data can be found in a series of books dedicated partially^{7,8} or entirely^{9–11} to ^{31}P NMR. A number of reviews^{12–14} dealing with the application of ^{31}P NMR to transition metal complexes with phosphorus ligands, and a review¹⁵ describing the main developments in ^{31}P NMR of transition metal–phosphine complexes in the period 1970–1977, are available.

With modern spectrometers and using all instrumental and relaxation aids phosphorus compounds at 200 ppm and even 5 ppm concentration levels can be detected by ^{31}P NMR.⁹ Due to this capability, ^{31}P NMR spectroscopy has also gained importance as an analytical tool in biology and medicine. The work in this area is documented by a series of reviews^{16–21} and books.^{22,23}

2 NUCLEAR PROPERTIES AND STANDARDIZATION

The important properties of the ^{31}P nucleus for NMR spectroscopy are given in Table 1. Since phosphorus compounds are generally reactive, no suitable internal reference compound

Table 1 Properties of the ^{31}P Nucleus^{7,8,10}

Natural abundance, C (%)	100
Nuclear spin, I	$\frac{1}{2}$
Magnetic moment, μ (μ_N)	1.1316
Magnetogyric ratio γ ($10^7 \text{ rad T}^{-1} \text{ s}^{-1}$)	10.8394
NMR frequency at 2.35 T (MHz)	40.480
Receptivity relative to that of ^1H , D^P	6.63×10^{-2}
Receptivity relative to that of ^{13}C , D^C	3.77×10^2

is available for general use. Phosphorus-31 chemical shifts are referenced to 85% aqueous H_3PO_4 as an external standard. According to the present sign convention shifts are given positive for signals appearing at higher frequency (lower field) with respect to that of the standard. Great care is recommended, however, when using data from the older literature, since there was a change in sign convention in the mid-1970s.

A disadvantage of 85% H_3PO_4 as a standard is its broad resonance signal. A number of secondary external standards, giving much sharper signals, are therefore in use: P_4O_6 ($\delta^{31}\text{P} = 112.5$), $\text{P}(\text{OMe})_3$ ($\delta^{31}\text{P} = 140.4$), $\text{PO}(\text{OMe})_3$ ($\delta^{31}\text{P} = -2.4$), $[\text{P}(\text{OH})_4]\text{ClO}_4$ ($\delta^{31}\text{P} = -0.1$), $\text{Na}_2[\text{CH}_2(\text{PO}_3\text{H})_2]$ in D_2O ($\delta^{31}\text{P} = 16.7$), $(\text{NEt}_4)_2\text{HPO}_4$ in H_2O ($\delta^{31}\text{P} = 2.1$).^{8,9} In some cases D_3PO_4 ($\delta^{31}\text{P} = 0.3$) and $(\text{CH}_3)_3\text{PO}$ ($\delta^{31}\text{P} = 72.6$) are used as internal standards.^{8,9} Alternatively the ^2H internal lock signal can be used to obtain accurate chemical shifts referenced to $\text{Si}(\text{CH}_3)_4$ or to an idealized shift for 85% H_3PO_4 . However, there is little agreement on Ξ for 85% H_3PO_4 with values ranging from 40 480 720 to 40 480 754 Hz.^{7,9} An absolute ^{31}P shielding scale is based on gas phase measurements of PH_3 .²⁴

Normally the reported ^{31}P chemical shifts are not corrected for diamagnetic susceptibility. In addition temperature, solvent, and concentration dependence of $\delta^{31}\text{P}$ for both the reference compound and the compounds under study, may be important. Thus variations in reported chemical shifts for the same compound of up to ± 10 units can be encountered in the literature.^{7–10}

Measurements of the nuclear Overhauser enhancement show a wide variation extending from zero to the theoretical maximum of 124%.^{8,10,25}

Spin–lattice relaxation times T_1 of phosphorus compounds vary mostly between 1 and 30 s and can depend strongly on solvent, temperature, and concentration. Compilations of T_1 data for simple phosphorus compounds are found in Mason,⁸ Verkade and Quin,⁹ and Berger et al.¹⁰ Typical values are ~ 1.3 s for RPH_2 , 3–9 s for $\text{P}(\text{OR})_3$, 3–6 s for PX_3 ($X = \text{halogen}$), 2–9 s for $[\text{R}_4\text{P}]\text{X}$, 10–31 s for R_3P , 6–30 s for $\text{PO}(\text{OR})_3$, and 2–11 s for R_3PO .⁹ For a number of three-coordinated phosphorus compounds the spin rotation mechanism has been shown to account for T_1 at ambient temperature, while at low temperatures dipolar contributions become important.⁸ However, $\text{P}_2t\text{-Bu}_4$ relaxes by a dipolar mechanism even at ambient temperature. Going to four-coordination the relative contribution of the spin rotation mechanism decreases and is still important in the five-coordinated species $\text{PCl}_n\text{Ph}_{5-n}$ ($n = 2–4$) and the PF_6^- ion. A rare example, in which chemical shift anisotropy plays an important role in relaxation, is represented by Ph_3PO .⁸

3 EXPERIMENTAL TECHNIQUES

Due to its favorable nuclear properties ($I = 1/2$, high NMR frequency and high receptivity), the ^{31}P nucleus is easy to observe and no particular instrumental equipment is required. Early ^{31}P NMR spectra of solutions were recorded on continuous wave instruments and were often poorly resolved. Now practically all data are obtained with modern FT NMR spectrometers, equipped either with multinuclear probes or with separate pretuned probes for ^{31}P observation, yielding highly resolved spectra with $\Delta\nu_{1/2}$ often below 1.0 Hz. The optimum pulse duration depends on the relaxation time T_1 of the ^{31}P nucleus and the acquisition time T_{ac} . It has been recommended to set the pulse duration at $\cos^{-1}(e^{-T_{\text{ac}}/T_1})$.²⁶ Routine ^{31}P NMR spectra are obtained with broadband proton decoupling using a rapid pulse repetition (1 s) and a short pulse angle (30°).

A large number of special experimental NMR techniques have been applied to the ^{31}P nucleus including spin tickling,⁹ selective²⁷ and broadband⁹ ^{31}P decoupling, SPT,⁹ COSY,⁹ reverse shift heterocorrelated NMR spectroscopy,^{9,28} homonuclear^{9,29} and heteronuclear^{9,30} J resolved two-dimensional NMR spectroscopy, EXSY,³¹ and Hahn-echo extended pulse sequences.³² The CP MAS technique is widely used to obtain solid state ^{31}P NMR spectra.^{9,33} Liquid crystal ^{31}P NMR spectra of several cyclopolyphosphines $(\text{RP})_n$ and of other trivalent and pentavalent phosphorus compounds have been reported.⁹ In a few cases reactions of phosphorus compounds have been studied by CIDNP.³⁴

For ^{31}P measurements at variable temperature a 0.1 M solution of triphenylphosphine and triphenylphosphine oxide in toluene- d_8 has been recommended as a shift thermometer. At an operating frequency of 40 MHz the change in $\delta^{31}\text{P}$ is 1.3 Hz per degree.³⁵

4 CHEMICAL SHIFTS

The range of ^{31}P chemical shifts for liquid, dissolved, or gaseous diamagnetic phosphorus compounds covers nearly 2000 ppm and extends from +1362 for $t\text{-BuP}[\text{Cr}(\text{CO})_5]_2$ to -552 for gaseous P_4 . If dissolved paramagnetic compounds are included, it widens to about 4700, with +3471 for the complex $[(\text{C}_4\text{Me}_4\text{P})_2\text{U}(\text{BH}_4)]_2$ on the high-frequency side and -1219 for $\text{OsCl}_4(\text{PBu}_2\text{Ph})_2$ on the low-frequency side.^{9,10} The characteristic ranges of $\delta^{31}\text{P}$ for one- to six-coordinated phosphorus compounds are shown in Figure 1. For pentavalent phosphorus the shift ranges are relatively narrow, and shielding of the phosphorus nucleus increases as its coordination number increases from 3 to 6. No such dependence is found for the trivalent phosphorus and, except for one-coordinated phosphorus compounds, the shift ranges are much wider.^{6,36} Detailed bar charts showing the dependence of $\delta^{31}\text{P}$ for individual classes of phosphorus compounds on the type of atoms bonded to phosphorus can be found in Tebbly⁶ and Mason.⁸

According to a semiempirical treatment proposed by Van Wazer and co-workers^{3,37} phosphorus chemical shifts can be interpreted in terms of three contributions: the bond angles at the phosphorus atom, the electronegativity of the substituents, and the extent of π bonding. If only one parameter is being changed at a time, useful correlations

Figure 1 Typical ranges of $\delta^{31}\text{P}$ for differently coordinated phosphorus compounds

within a class of compounds are obtained.^{8,10} Thus for cyclopolyphosphines $(\text{RP})_n$ the phosphorus chemical shift is almost linearly correlated with the average endocyclic PPP bond angles, and definite ranges can be established for $n = 5$ ($\delta^{31}\text{P} = +50$ to -10), $n = 4$ ($\delta^{31}\text{P} = -50$ to -80), and $n = 3$ ($\delta^{31}\text{P} = -30$ to -180). The only known compound for $n = 6$, $(\text{PhP})_6$, ($\delta^{31}\text{P} = -22$) also fits this correlation.^{8,10} Linear shift/bond angle correlations have also been reported for the basal phosphorus atoms in cage molecules of the series $\text{P}_4\text{S}_x\text{Se}_{3-x}$ ($x = 0-3$), $\text{P}_y\text{As}_{4-y}\text{S}_3$, and $\text{P}_y\text{As}_{4-y}\text{Se}_3$ ($y = 0-4$)³⁸ and for differently substituted cyclotriphosphines.³⁹ For $\delta^{31}\text{P}$ of *tert*-phosphines an additive relationship for the alkyl substituents is found; deshielding of phosphorus increases in the order $\text{Me} < \text{Et} < i\text{-Pr} < t\text{-Bu}$.⁷ More additive relationships have been reported for $\delta^{31}\text{P}$ in polyphosphines P_nH_{n+2} ,⁴⁰ primary⁴¹ and secondary phosphines,⁴² and alkyl phosphonium salts.⁴² Additive relationships often fail, however, when π bonding or electronegative substituents are involved.^{7,8,10}

Theoretical calculations of ^{31}P chemical shifts for a series of simple phosphorus compounds by semiempirical methods and for PH_3 by ab initio methods have been reviewed.⁹ Using the IGLO method, ab initio calculations of $\delta^{31}\text{P}$ for larger molecules have also been performed.⁴³

Isotope effects on ^{31}P nuclear shielding caused by ^2H , ^{13}C , ^{15}N , ^{18}O , $^{34,36}\text{S}$, $^{35,37}\text{Cl}$, and $^{79,81}\text{Br}$ have been observed.^{44,45}

In 2-amino-1,3,2-dioxaphosphorinane 2-chalcogenides the isotopic effect of ^{15}N on $\delta^{31}\text{P}$ is larger for the shorter equatorial than for the longer axial P–N bond.⁴⁴

4.1 One-Coordinate Phosphorus

The range of ^{31}P chemical shifts for one-coordinated phosphorus compounds (phosphaalkynes $\text{R}-\text{C}\equiv\text{P}$ ^{6,36,46,47} and $[2,4,6-t\text{-Bu}_3\text{C}_6\text{H}_2-\text{N}\equiv\text{P}][\text{AlCl}_4]$ ⁴⁸) extends mainly from +96 to –70. Depending on R, shielding of the phosphorus nucleus in phosphaalkynes increases generally in the order $(\text{CH}_3)_3\text{Si} < \text{aryl}, \text{H} < \text{alkyl} < \text{amino} < \text{F}$.^{36,46} A linear relationship results for $\delta^{31}\text{P}$ and δN of identically substituted phosphaalkynes and nitriles.³⁶ Phosphorus-31 solid state NMR investigations of $2,4,6-t\text{-Bu}_3\text{C}_6\text{H}_2-\text{C}\equiv\text{P}$ ⁴⁹ and $[2,4,6-t\text{-Bu}_3\text{C}_6\text{H}_2-\text{N}\equiv\text{P}][\text{AlCl}_4]$ ⁵⁰ have been published.

4.2 Two-Coordinate Phosphorus

Compilations of $\delta^{31}\text{P}$ are available for the large number of two-coordinated phosphorus compounds.^{6,51–53} Values of $\delta^{31}\text{P}$ extend from +954 to –363 with most of them between +600 and –300. This wide shift range corresponds to a variation of phosphorus character from a phosphonium type with a high-frequency chemical shift to a phosphide type with a low-frequency chemical shift. The overall charge of the molecule seems not to be important.^{6,51} Values of $\delta^{31}\text{P}$ of fully unsaturated phosphorus heterocycles extend from +495 to –5 with most of the shifts between +300 and +50.^{6,36,52,53}

Linear correlations are found for $\delta^{31}\text{P}$ in aryl-substituted phosphaalkenes with Hammett constants and for $\delta^{31}\text{P}$ in iminophosphines with the $n \rightarrow \pi^*$ transition energies. Values of $\delta^{31}\text{P}$ of $=\text{PR}$ in various acyclic compounds and $\delta^{13}\text{C}$ and $\delta^{77}\text{Se}$ of the corresponding $=\text{CH}_2$ and $=\text{Se}$ compounds also give fair linear correlations. More linear correlations are found for the exchange of $=\text{P}$ –for $=\text{N}$ –in both acyclic and heterocyclic compounds and for $=\text{CH}$ –in otherwise identical heterocycles.³⁶

Solid state ^{31}P NMR spectra of a diphosphene,⁵⁴ a phosphaalkene,⁴⁹ and benzo-anellated heterophospholes⁵⁵ have been reported.

4.3 Three-Coordinate Phosphorus

The ^{31}P chemical shifts of three-coordinate trivalent phosphorus cover a wide range from +282 to –461 with most of the shifts between +220 and –290.⁶ Ranges of $\delta^{31}\text{P}$ for individual types of P (III) compounds are found in Tebby,⁶ Mason,⁸ and Berger et al.¹⁰ Values of $\delta^{31}\text{P}$ of conformationally mobile di- and polyphosphines are likely to be temperature-dependent. In alkenic-substituted phosphines the ^{31}P nucleus is more shielded in the Z- compared with the E-isomer (effect of steric compression). A nearly linear correlation is found between $\delta^{31}\text{P}$ in $\text{Ph}_2\text{P}-\text{R}$ and $\delta^{13}\text{C}$ in CH_3-R .^{8–10}

For three-coordinate pentavalent phosphorus $\delta^{31}\text{P}$ ranges (excluding extreme values) essentially from +300 to +40 and is thus found at higher frequency than $\delta^{31}\text{P}$ of higher-coordinated phosphorus(V).^{6,36,56} In σ^3 -phosphoranes of the type $\text{R}-\text{PXY}$, depending on the double bonded substituents X and Y, phosphorus shielding generally increases in the order $\text{ML}_n < \text{S} < \text{Se} < \text{CR}_2 < \text{NR} < \text{O}$.^{36,56}

4.4 Four-Coordinate Phosphorus

The ^{31}P chemical shift range of pentavalent tetracoordinate phosphorus extends essentially between +140 and –90 with a few extreme values for phosphonium compounds of up to –308.⁶ Shift ranges for individual classes of compounds can be found in Tebby,⁶ Mason,⁸ and Berger et al.¹⁰

A number of phosphonic and phosphinic acids, inorganic phosphates, and polyphosphates have been investigated by solid state ^{31}P NMR spectroscopy.¹⁰ In the case of polyphosphates, the different $\delta^{31}\text{P}$ values of the terminal and bridging phosphate groups have been interpreted in terms of the electronegativity difference between terminal and bridging oxygen atoms (estimated at 0.4) and the difference in π -bonding order.⁵⁷ A linear relationship results between $\delta^{31}\text{P}$ and the P–O bond strength in inorganic phosphates.⁵⁸

In phosphates and phosphate esters, as well as in their thio derivatives a clear dependence of $\delta^{31}\text{P}$ on the XPX angle (X = O, S) is observed. In phosphoric and phosphonic acids, and in mono- and dinucleotides the ^{31}P chemical shift shows a dependence on pH. Good linear Hammett correlations and a linear $\delta^{31}\text{P}/\delta^{13}\text{C}$ relationship for $[\text{Ph}_3\text{PR}]\text{X}$ and CH_3-R have been reported.¹⁰

In contrast to the tetracoordinate phosphorus(V), the ^{31}P chemical shift range for the tetracoordinate trivalent phosphorus (phosphoranide-type phosphorus) is much larger and extends from +222 to –242.⁶

4.5 Five-Coordinate Phosphorus

The chemical shift of five-coordinate phosphorus covers a range between +31 and –195 with the majority of shifts between 0 and –80.⁶ A temperature dependence of the NMR spectra is often encountered, due to intermolecular^{9,59} or intramolecular (pseudorotation)^{9,60} ligand exchange or to hindered rotation.^{9,61}

4.6 Six-Coordinate Phosphorus

The chemical shifts of six-coordinate phosphorus are found between –57 and –441 with most of the shifts between –80 and –290.⁶ The major factors determining the chemical shifts are electronegativity and anisotropic effects of the substituents. Increasing the overall charge of the species from +1 through zero to –1 shifts $\delta^{31}\text{P}$ to lower frequency, while incorporation of the phosphorus in a five-membered ring results in a shift of $\delta^{31}\text{P}$ in the opposite direction.^{6,9}

5 COUPLING CONSTANTS

Scalar spin–spin couplings of phosphorus to almost all elements of the Periodic Table are known, and remarkably large coupling constants up to 17000 Hz (!) have been observed. Compilations of phosphorus–element coupling constants can be found in several books.^{7–10,62} Representative values are contained in most of the compilations of ^{31}P chemical shift data.^{4–6,51–53} Specialized reviews on phosphorus–phosphorus,⁶³ phosphorus–hydrogen,⁶⁴ and phosphorus–carbon^{65,66} coupling constants are available.

Table 2 Observed Phosphorus–Phosphorus Coupling Constants

Coupling constant	J (Hz)	References
$^1J(\text{P}^{\text{III}}, \text{P}^{\text{III}})$	–55 to –670	8–10, 51–53, 63
$^1J(\text{P}^{\text{III}}, \text{P}^{\text{V}})$	–157 to –684	8–10, 63
$^1J(\text{P}^{\text{V}}, \text{P}^{\text{V}})$	–67 to +766	8–10, 63
$^2J(\text{P}^{\text{III}}, \text{P}^{\text{III}})$	–35 to +665	8–10, 63
$^2J(\text{P}^{\text{III}}, \text{P}^{\text{V}})$	–28 to +150	8–10, 63
$^2J(\text{P}^{\text{V}}, \text{P}^{\text{V}})$	11 to 210	8–10, 63
$^3J(\text{P}, \text{P})$	0 to 227	8–10, 63
$^4J(\text{P}, \text{P})$	2 to 35	9, 10, 63
$^5J(\text{P}, \text{P})$	5 to 9	67
$^6J(\text{P}, \text{P})$	3 to 12	67, 68
$^7J(\text{P}, \text{P})$	1 to 8	67
$^8J(\text{P}, \text{P})$	1 to 2	67
$^9J(\text{P}, \text{P})$	4	67

More information on specific phosphorus–element coupling constants can be found in the references in Tables 2 and 3.

It is generally observed, that the values of the reduced coupling constants $^nK(\text{P}, \text{X})$ decrease in the order $^1K(\text{P}, \text{X}) \gg ^3K(\text{P}, \text{X}) > ^2K(\text{P}, \text{X}) > ^4K(\text{P}, \text{X})$.⁹ In many cases, however, the order of $^3K(\text{P}, \text{X})$ and $^2K(\text{P}, \text{X})$ is reversed, due to structural factors. Coupling constants over more than four bonds are normally two or more orders of magnitude smaller than $^1K(\text{P}, \text{X})$. In special cases and particularly in compounds with a delocalized π system long-range coupling constants $^nJ(\text{P}, \text{P})$ for $n = 5$ – 9 ^{67, 68} and $^nJ(^{31}\text{P}, ^{13}\text{C})$ up to $n = 7$ ⁶⁹ have been observed.

The presence of a lone pair of electrons at the phosphorus atom or at the atom coupled with it seems to be associated with a negative one-bond reduced coupling constant $^1K(\text{P}, \text{X})$. An exception is provided by $^1K(^{31}\text{P}, ^1\text{H})$, however, which is positive. The magnitude of $^1K(\text{P}, \text{X})$ increases with increasing electronegativity of the substituents regardless of its sign. Linear relationships have been found between $^1K(\text{P}, \text{X})$ and the sum of the electronegativity of the substituents at the phosphorus atom for $^1K(^{183}\text{W}, ^{31}\text{P})$, $^1K(^{77}\text{Se}, ^{31}\text{P})$, $^1K(^{95}\text{Mo}, ^{31}\text{P})$, $^1K(^{31}\text{P}, ^{31}\text{P})$, $^1K(^{31}\text{P}, ^{13}\text{C})$, and $^1K(^{31}\text{P}, ^1\text{H})$.^{9, 10, 70}

In molecules with a trigonal bipyramidal geometry $^1K(\text{P}, \text{X})$ through the shorter equatorial bond is larger than through the longer axial bond.^{9, 10, 71} In transition metal–phosphine complexes the one-bond phosphorus–metal coupling constant is found to increase with decreasing *trans*-effect of the ligand in the *trans*-position to the phosphorus atom in the order $\text{MePh}_2\text{Si} > \text{Ph} > \text{Me} \gg \text{R}_3\text{P} > (\text{PhO})_3\text{P}$, $\text{CN} > \text{Et}_3\text{As} > \text{NO}_2 > \text{amine}$, NCO , $\text{NCS} > \text{Cl}$, Br , $\text{I} > \text{ONO}_2 > \text{F}$.^{9, 10} A bond angle and dihedral angle dependence of $^1K(\text{P}, \text{X})$ has also been discussed.^{5, 9, 72, 73}

Geminal coupling constants $^2K(\text{P}, \text{X})$ show, in principle, the same dependences as $^1K(\text{P}, \text{X})$; the signs are often reversed, however. For the three-coordinate trivalent phosphorus there is a dependence of $^2K(\text{P}, \text{X})$ on the dihedral angle between the phosphorus lone pair and the X nucleus,⁷³ which has been investigated for $^2J(^{31}\text{P}, ^{31}\text{P})$, $^2J(^{31}\text{P}, ^{13}\text{C})$, and $^2J(^{31}\text{P}, ^1\text{H})$. For tetracoordinate phosphorus a similar dependence is found with an electronegative substituent in place of the lone pair.⁹

Of general importance is the dependence of vicinal reduced coupling constants $^3K(\text{P}, \text{X})$ on the dihedral angle between the phosphorus and the X nucleus (Karplus relationship), which has been investigated for a number of compounds. In all

cases a minimum near 90° and maxima at 0° and 180° are observed.^{9, 10, 74}

5.1 Phosphorus–Phosphorus Coupling Constants

Typical ranges for P,P coupling constants are given in Table 2. The value of $^1J(^{31}\text{P}, ^{31}\text{P})$ is negative between trivalent phosphorus atoms and, where the sign is known, also between trivalent and pentavalent phosphorus atoms. Between pentavalent phosphorus atoms $^1J(^{31}\text{P}, ^{31}\text{P})$ is often positive. One-bond phosphorus–phosphorus coupling constants show a large stereochemical dependence on rotation about the P–P bond, especially when there are lone pairs at the phosphorus atoms.^{8–10}

Geminal P(III), P(III) coupling constants are mostly positive and extend up to +665 Hz. In acyclic compounds geminal P(III), P(V) couplings range mainly between +50 Hz and +150 Hz, whereas for cyclic compounds smaller and negative values are found. The value of $^2J(^{31}\text{P}, ^{31}\text{P})$ between pentavalent phosphorus atoms in acyclic compounds is generally small (11–43 Hz), but can assume large values up to +210 Hz in cyclic compounds.⁸

5.2 Phosphorus Couplings to Other Nuclei

Typical ranges for the coupling constants of phosphorus to other elements of the Periodic Table are given in Table 3. The signs of the coupling constants, where known, have also been included. The value of $^1J(^{31}\text{P}, ^1\text{H})$ tends to increase with increasing oxidation state and coordination number of phosphorus; the individual ranges overlap considerably, however.⁷⁰ One-bond phosphorus–fluorine coupling constants show the opposite trend, in accord with the opposite signs of $^1J(^{31}\text{P}, ^1\text{H})$ and $^1J(^{31}\text{P}, ^{19}\text{F})$.^{9, 10} An isotope effect of ^2H on $^1J(^{31}\text{P}, ^1\text{H})$ has been reported.¹⁰³ The $^1J(^{31}\text{P}, ^{15}\text{N})$ value is positive (+24 to +105 Hz) in trivalent, generally positive (–44 to +60 Hz) in tetravalent, and negative (–40 to –80 Hz) in pentavalent phosphorus compounds. The $^1J(^{77}\text{Se}, ^{31}\text{P})$ value is larger for a phosphorus–selenium double bond (–500 to –1200 Hz) than for a single bond (–100 to –500 Hz). Similarly $^1J(^{125}\text{Te}, ^{31}\text{P})$ is larger for $\text{P}=\text{Te}$ (1324–2290 Hz) than for $\text{P}-\text{Te}$ (80–996 Hz).^{8, 9} Exceptionally large values, reaching orders of magnitude of the corresponding one-bond coupling constants, are observed for $^2J(^{77}\text{Se}, ^{31}\text{P})$,⁹² $^2J(^{119}\text{Sn}, ^{31}\text{P})$,¹⁰ $^2J(^{205}\text{Tl}, ^{31}\text{P})$,¹⁰² and $^2J(^{207}\text{Pb}, ^{31}\text{P})$ ¹⁰⁴ in transition metal complexes.

6 APPLICATIONS OF ^{31}P NMR SPECTROSCOPY

Phosphorus-31 NMR spectroscopy has been used to monitor the progress of chemical reactions and exchange equilibria since its early days. Today ^{31}P NMR spectroscopy is a powerful diagnostic tool in practically all areas of preparative chemistry where phosphorus is present. Alone, or in combination with the NMR spectroscopy of other nuclei, it is mostly used for the identification and structure elucidation of phosphorus compounds. The enantiomeric purity of chiral alcohols, thiols (via the corresponding phosphites and thiophosphonates), and phosphines is conveniently checked by ^{31}P NMR. Based on

Table 3 Observed Coupling Constants of Phosphorus to Other Nuclei

1 INTRODUCTION

Polymorphism is ubiquitous in solid state chemistry, commonly occurring for a very wide range of materials. Polymorphs are different solid forms (usually crystalline) of a given compound. The differences lie in solid state structure, i.e. in the spatial arrangement of the atoms or molecules. They may be relatively minor (e.g. variations in mutual orientations of molecules) or major (leading, for instance, to substantially different atomic arrangements). Sometimes other terms are used for the phenomenon. Thus, when concerning different forms of the elements, the word allotrope is used, instead of polymorph. Also, polymorphs which have structures differing in the stacking sequence of layers (for example, in silicon carbide) are called polytypes.

A somewhat similar phenomenon is the ability of many compounds to incorporate solvent molecules in their structure during crystallization from solution. Thus compounds frequently exist in both anhydrous and hydrated forms, the crystal structures of which may be essentially identical or profoundly different. Other solvent molecules, such as acetone and chloroform, may be similarly incorporated. Ultimately this relates to the existence of clathrates, for which the structure may only be stable when both host and guest molecules are present. Sometimes hydrates lose water readily; on other occasions anhydrous forms may be hygroscopic. Although this article will concentrate on true polymorphism, the 'pseudopolymorphism' of solvates, which can carry similar NMR connotations, will be mentioned at times.

Of course, another closely-related topic is that of phase changes and phase diagrams, together with similar matters concerning the formation and interchange of polymorphic forms. These questions will be largely ignored in the present article. Under given conditions of temperature, pressure, etc., only one polymorph will clearly be favored by thermodynamic considerations. Frequently, however, kinetics of interconversions will be slow, and several forms will exist at ambient temperature and pressure for times in excess of the minimum required to obtain NMR spectra. Such metastable forms may be obtained, for instance, by crystallization from a solvent or by quenching from a temperature at which they are stable. The present article will concentrate on NMR data obtained under standard

working conditions (atmospheric pressure and ambient temperature).

Cases of polymorphism and related phenomena may be divided into those involving molecular crystals and those relating to macromolecular structures (in one, two, or three dimensions). Of course, the bonding in the latter implies that interconversion between forms (e.g. between graphite and diamond) is extremely difficult. Indeed, it might be argued that cases of macromolecular structural differences, which require bond-breaking for interconversion (as for silicon carbide) are not properly labeled as polymorphic since they are more analogous to some types of isomerism in organic compounds. However, although interconversions between molecular polymorphs are usually relatively easy, it must not be assumed that intermolecular forces are negligible. Frequently they involve hydrogen bonding, with substantial energies.

Polymorphism is particularly important, and has been extensively investigated by NMR, for pharmaceutical compounds, for silicates and zeolites, for polymers (including naturally occurring materials such as cellulose and chitosan, as well as synthetic polymers), and for ceramic materials.

2 APPLICABILITY OF NMR

Since the electronic environments of corresponding atoms in different polymorphs of the same compound differ, the NMR chemical shifts will be in principle distinguishable. Indeed, the total NMR spectrum can clearly act as a fingerprint to identify polymorphic forms. Such differences are expected to be similar in magnitude to the crystallographic splittings observed when molecules or atomic groupings of the same chemical type are in locations in the unit cell unrelated by symmetry. The 'fingerprint' is of the crystallographic asymmetric unit, and simply counting the number of resonances may, on occasion, suffice to distinguish between polymorphs.

The techniques most commonly used to distinguish polymorphs are DSC, IR, and powder XRD, but all three have disadvantages. The DSC method is very crude, since it gives little or no chemical information. IR spectroscopy often suffers from lack of resolution and from difficulties in interpreting intensities. Powder XRD is often the preferred technique, but it is not sensitive to poorly crystalline or amorphous forms. NMR does not suffer from any of these problems, and the only drawback is the cost of the equipment.

Polymorphs often differ in molecular-level mobility, and hence in NMR relaxation times, but these are unlikely to be used as distinguishing features, except perhaps for polymeric systems.

3 MOLECULAR POLYMORPHS

The principal area of investigation of molecular polymorphism is that of pharmaceutical compounds. This is for very practical reasons: polymorphs sometimes show differing physiological activity (largely as a result of differences in rates of dissolution) and government regulations therefore require pharmaceutical companies to identify carefully the polymorphic form of their products. Moreover, very small changes in

conditions of preparation can readily result in a difference in polymorphic form, and scale-up can reveal problems not found in laboratory synthesis, so that an understanding of polymorphic variations is very important in pharmaceutical chemistry.

The first application of ^{13}C CP MAS NMR to pharmaceutical polymorphism appears to be that reported by Balimann et al.¹ in 1981, which featured spectra of two forms of Nolvadex (the ICI trade name for the generic tamoxifen). In the late 1980s and early 1990s the groups of Byrn^{2,3} and of Harris⁴⁻⁶ were particularly active in this area.

Steroids appear to be particularly prone to give rise to polymorphic forms. Cortisone acetate (**1**) is a typical example. A substantial number of polymorphs and solvated forms are known, and seven have been studied⁴ by MAS NMR. Three of the polymorphs are anhydrous, and Figure 1 illustrates the ^{13}C CP MAS spectra for the high-frequency region (containing resonances from C-3, C-5, C-11, C-20 and C-22).

Immediately, two important conclusions can be made:

1. NMR readily distinguishes the three anhydrous forms (as it does the five hydrates and other solvates).
2. Whereas Forms I and II have asymmetric units consisting of a single molecule (since only five signals are seen in this region), Form III is more complex. In fact, expanded-scale spectra for all the carbon resonances show that Form III has three molecules in the asymmetric unit.

One can go further when peak assignments are firmly established. The apparent variation in the relative intensities of the two peaks on the right in Figure 1(a) and (b) arises from differing spinning sideband intensities. Complete analysis of the spinning sideband manifolds (at low spin rates) shows that C-5 and C-22 have distinguishable shielding anisotropies and asymmetries, which in turn indicates that the order of their isotropic chemical shifts is interchanged between Forms I and II. This variation can be correlated with hydrogen

Figure 1 Carbon-13 CP MAS NMR spectra⁴ (high-frequency region only) of three polymorphs of cortisone acetate (**1**) at 50.3 MHz

Table 1 Isotropic Chemical Shifts^a for C-3, C-5, and C-22 of the Anhydrous Polymorphs of Cortisone Acetate

Carbon	Form I	Form II	Form III
C-3	202.8 ^b	198.9	203.0 ^c , 203.0 ^c , 198.2
C-5	175.7	171.0	173.7, 173.7, 166.9
C-22	169.8	175.2 ^b	174.3 ^c , 171.5, 170.3

^aGiven as δ_{C} (ppm).

^bShown by X-ray crystallography to be the acceptor site for hydrogen bonding.

^cConcluded from the NMR evidence to be the acceptor site for hydrogen bonding.

bonding,^{2,4} which causes an increase in chemical shift of 3–4 ppm at the acceptor carbonyl carbon resonance. Table 1 shows the assignments for carbons C-3, C-5 and C-22 for the three anhydrous forms, and indicates the known acceptor positions for hydrogen bonding. One can conclude that, of the three molecules in the asymmetric unit of Form III, two are hydrogen bonded at C-3 and the third, in contrast, at C-22. It may be noted that conjugation appears to relay the effect of hydrogen bonding on the chemical shift from C-3 to C-5.

This example illustrates how polymorphic form can affect chemical shifts. Unfortunately, matters are not often so simple. The differences in chemical shifts between analogous carbons for different polymorphs may arise either from *intermolecular* effects (packing, direct influence of neighboring molecules, hydrogen bonding, etc.) or *intramolecular* effects (variations in geometry and/or conformation). There is rarely any way that NMR can distinguish between the two influences. Of course, if crystal structures are known from X-ray studies, then knowledge of influences on chemical shifts obtained from solution state studies or by theory can be brought to bear. A case where intramolecular differences (but correlated with intermolecular differences!) are thought to be important is that of 4'-methyl-2'-nitroacetanilide (**2**), which exists in two forms (white and yellow), both of which have been subjected to study by single-crystal X-ray diffraction. In the white form, both the amide and nitro groups are in planes at a substantial angle (ca. 44°) to the plane of the aromatic ring, giving restricted conjugation and preventing intramolecular hydrogen bonding. On the other hand, the yellow form (with two molecules in the asymmetric unit) has more nearly coplanar groups (dihedral angles between 12° and 31°), allowing intramolecular hydrogen bonding between the amide NH and one of the nitro group oxygens. These facts suffice to explain the differences in chemical shifts between the polymorphs.⁵ For example, the white form (C–NO₂ dihedral angle, 44.0°) has $\delta(\text{C-2}) = 144.1$ ppm whereas the yellow form (C–NO₂ dihedral angles, 18.0° and 12.3°) gives $\delta(\text{C-2}) = 135.9$ and 133.0 ppm (presumably respectively).

Certain simple but important measurements can be made of polymorphism via the fingerprinting ability. For example:

1. Mixtures of polymorphs can be readily studied and minor components can be quantified,⁴ in favorable cases down to the 1% level.
2. NMR spectra can be used to monitor the polymorphic variations produced by different formation conditions (e.g. different rates of crystallization produced by cooling a solution quickly or slowly).⁴
3. Polymorphism can be studied directly in pharmaceutical tablets. Saindon et al.³ have pointed out that the CP MAS technique can be used to discriminate against signals deriving from the excipient.

The combination of single-crystal XRD and CP MAS NMR for the study of polymorphism is particularly powerful. The former can give precise atomic positions but is frequently feasible for only some of the forms of a product (because of difficulties in growing suitable crystals). NMR, however, can almost always be relied upon to yield spectra of all polymorphs available in sufficient quantity, and interpretation is greatly aided by X-ray information on any one form. For example, of the two forms of fosinopril sodium, one was examined using single-crystal X-ray diffraction techniques, then both were studied⁷ by CP MAS NMR of ¹³C. The results provided by NMR enabled the conclusion to be drawn that the environment of the acetal side chain of fosinopril sodium differed in the two polymorphs. In this case ³¹P CP MAS NMR was also used, and showed a significant chemical shift difference (2.2 ppm) between the forms.

It is possible to detect conformational disorder within polymorphs by CP MAS NMR. Thus Stoltz et al.⁸ have shown that peak intensities for the monohydrate of oxyphenbutazone give a site ratio consistent with X-ray results in terms of sterically-favored isomers. However, it must be said that since CP MAS NMR spectra are obtained on microcrystalline or powdered material, it is not easy to differentiate between mixed crystals and disorder in a single type of crystal.

Differences in bonding between polymorphs can sometimes be quite startling but readily detectable by NMR. Thus, for 2-aminobenzoic acid (**3**), ¹³C MAS NMR reveals⁹ that Form I gives two signals each for C-1 and C-2. These are at chemical shifts which are characteristic of the normal and zwitterionic structures (**3**)A and (**3**)B, respectively, indicating that the unit cell contains equal proportions of each form. On the other hand, Forms II and III give spectra showing that each has an asymmetric unit containing one molecule of structure (**3**)A only.

Interestingly, the ¹³C spectra of Forms II and III are so similar as to be virtually indistinguishable. In these cases, it is necessary to turn to nuclei other than ¹³C to differentiate. The proton CRAMP spectra of the two forms are, in fact, very different (Figure 2). Form II of the compound gives a

Figure 2 Proton CRAMP spectra⁹ of two polymorphs of 2-aminobenzoic acid (**3**) at 200.13 MHz. The sample of Form III contains a small amount of Form II, which gives rise to the hydrogen-bonded peak at δ 12.3 ppm. The peak at $\delta \sim 1.5$ ppm in each spectrum is due to an impurity in the Kel-F rotors used. The broad line (assigned to NH_2 and CO_2H protons) underlying the spectrum of Form III is clearly visible

strong signal at $\delta_{\text{H}} = 12.3$ ppm, indicative of a hydrogen-bonded CO_2H group (in agreement with single-crystal X-ray results). This is not present for Form III (the crystal structure of which is unknown)—from which it can be deduced that hydrogen bonding is probably absent. However, the situation is complicated by the fact that there are proton-exchange processes occurring, involving amino and (in some cases) carboxylic acid protons, at a rate comparable with the NMR timescale, producing broad bands underlying the sharper aromatic proton signals at ambient probe temperature.

4 POLYMORPHISM AND MOLECULAR MOBILITY

In addition to the effects on chemical shifts arising from differences in intermolecular environment and intramolecular geometry between molecules of different polymorphs, variations in molecular level motion can often also be detected. A case in point is illustrated in Figure 3, which shows ambient probe temperature ¹³C CP MAS spectra¹⁰ of two forms

Figure 3 Carbon-13 CP MAS spectra¹⁰ of two forms of bisphenol-A diacetate (**4**) at 50.3 MHz and ambient probe temperature. Signals not indicated by numbers in (a) [and corresponding peaks in (b)] are spinning sidebands

of bisphenol-A diacetate (**4**). Clearly, Form I gives a much more complex spectrum than Form II, as is consistent with the single-crystal X-ray results, which show that in the former case the asymmetric unit consists of two entire molecules. The second feature of importance is the breadth of the resonances for the aromatic CH carbons (C-4, C-5, C-7 and C-8) for Form II, which suggests there is substantial averaging, probably arising from 180° ring-flips of the phenylene rings (possibly by simultaneous motion of the two halves of the molecule). This suggestion is readily confirmed by variation of the temperature.

Such variable temperature ¹³C CP MAS NMR experiments have been used¹¹ to study the motion of a phenylene ring about the *para* axis of one form of sulfanilamide, (**5**). Just below room temperature the C-3/C-5 resonance (but not the C-2/C-6 signal) is observably split because the SO₂NH₂ substituent

is twisted with respect to the ring. An Arrhenius activation energy, E_a , of $63 \pm 4 \text{ kJ mol}^{-1}$ for the (assumed) 180° ring-flip was obtained. It should be noted that rapid motion of this type would not be detected by XRD.

An example from an entirely different area of chemistry concerns the polymorphism of phosphorus pentachloride, PCl₅. The stable form (Phase II) of this compound under normal conditions is ionic, with the structure PCl₄⁺ PCl₆⁻. Both ions are very mobile at ambient temperature, so that shielding anisotropy at the phosphorus nuclei is eliminated and the chlorine nuclei relax very rapidly. The latter effect causes self-decoupling of the chlorines and the net effect is that ³¹P MAS spectra consist¹² of two sharp lines, one for each anion. However, Phase III, which can also be studied at ambient probe temperature, has the stoichiometry [PCl₄]₂⁺[PCl₆]₂⁻Cl⁻. Since this form, like Phase II, contains PCl₄⁺ and PCl₆⁻ ions, the ³¹P MAS spectrum also consists of two bands, but at 81 MHz the resonances are broad and splittings arising from (Cl,P) coupling are seen at 36 MHz. Thus self-decoupling is substantially less efficient for Phase III than for Phase II, probably indicating more restricted rotational mobility for the ions in the former.

5 MACROMOLECULAR POLYMORPHS

Two types of example from widely different chemical areas should suffice to show some of the general features of polymorphism in macromolecular systems. Silicon carbide exemplifies the situation where the structure is three-dimensional so that interchange between forms is not feasible. The different polymorphs are essentially frozen-in at the time of preparation. All structures have alternating Si and C atoms, with all coordinations tetrahedral (though mostly not with the full symmetry). The structural differences between some of the forms can be appreciated from Figure 4, which shows a plane including the *c* crystallographic axis and alternating Si and C atoms in that plane for four forms of the material. It is evident that the detailed environments of all silicon atoms of the 2H form are equivalent, as is also the case for the β form (though β and 2H environments are not identical). However, the 4H form contains two types of Si and the 6H three types. The ²⁹Si spectra (Figure 5) show¹³ the expected number of signals for the four forms. Similar considerations apply to the ¹³C spectra. There is also a range of other forms. Assignment of the signals for the 4H and 6H polymorphs is not easy but has been made.^{13,14} The separate signals have different relaxation times, probably as a result of the presence of impurities. Silicon carbide is a case where the amorphous material can also exist, without sizable domains of any of the potentially ordered structures. Such material gives rise to broad ²⁹Si and ¹³C resonances, usually characterized by shorter values of *T*₁ than the crystalline material, probably because impurities tend to concentrate in amorphous regions.

Of course, silica provides the outstanding example of a compound with multiple polymorphs. Not only are there well-characterized crystalline forms (quartz, cristobalite, tridymite, etc.), together with the common amorphous glass, but it seems that many types of zeolites can be obtained with all aluminum atoms replaced by silicon so that they become silica polymorphs. Since zeolites are treated in other entries in this Encyclopedia they will not be discussed here. The book

Figure 5 Silicon-29 MAS NMR spectra¹³ of silicon carbide polymorphs at 59.58 MHz: (a) 3C (β); (b) 2H; (c) 4H; and (d) 6H

by Engelhardt and Michel¹⁵ contains a useful discussion of NMR studies of nonzeolitic silica polymorphs (pp. 170–175). The ^{29}Si chemical shifts cover a wide range ($\delta_{\text{Si}} \sim -107$ to -121 ppm), the variation being attributed to differences in mean SiOSi bond angles, α , an increase in shielding resulting from widening SiOSi angles. A number of specific relationships have been proposed,¹⁶ including (from theoretical considerations) $\delta_{\text{Si}} = -247.05\rho + 2.19$, where $\rho = \cos \alpha / (\cos \alpha - 1)$. Of course, many of the silica polymorphs differ in the number of different crystallographic sites. Coesite, for instance, gives two widely-spaced ^{29}Si signals ($\delta_{\text{Si}} = 108.1$ and

113.9 ppm), in accord with its structure.¹⁶ In contrast to all the four-coordinate silica polymorphs, stishovite, which contains six-coordinate silicon, gives a signal at $\delta_{\text{Si}} = -191$ ppm.¹⁶ As with silicon carbide, amorphous forms of silica (glass!) are well known.

Organic polymers may also show polymorphism. One of the early examples of CP MAS NMR related to the case of isotactic polypropene, which exists in several crystalline forms usually as domains separated by amorphous material. In effect, the chains constitute infinite one-dimensional bonded structures with weaker forces between the chains. The systems therefore are intermediate between the molecular polymorphs discussed in Section 3 and the infinite three-dimensional structures of SiC and SiO₂. The structure of the α form of polypropene is shown in Figure 6(a). The helical polymer units occur as pairs of interlocking chains with opposing handedness. This creates a situation where there are two distinct methyl sites, with two-thirds of the groups in a given helix facing the companion helix, and the remaining third facing outwards. Thus a 2:1 doublet is expected for the methyl carbons, and this is observed¹⁷ in practice. A similar situation obtains for the CH carbons.

In contrast, the crystal structure of the β form contains separate groups of helices of the two types of handedness, with no pairing [Figure 6(b)]. The NMR spectrum therefore lacks the well-defined splitting shown by that of the α form.

Figure 6 Diagrammatic crystal structures for two forms of isotactic polypropene: (a) α form; (b) β form. The figures show projections of the chains perpendicular to their axes, with the corners of the triangles indicating the positions of methyl groups. The arrows represent the handedness of the helices

Of course, isotactic polypropene also contains a significant proportion of amorphous material which, as usual, gives rise to somewhat broadened CP MAS ^{13}C lines. The differences between the α and β forms of isotactic polypropene arise from intermolecular packing of the polymer chains. Far greater differences occur, as expected, in NMR spectra^{17,18} for polymer forms differing in tacticity (such as isotactic and syndiotactic polypropene). However, differences in tacticity are not normally classed under polymorphism.

Biochemical polymers such as cellulose and chitosan also give rise to polymorphism, which has been studied by solid state NMR methods.^{19,20}

1 INTRODUCTION

Spectral editing techniques in NMR in general are methods that aid the spectroscopist in assigning or simplifying complex high-resolution spectra. Most approaches to spectral editing have been developed in the context of NMR of ^{13}C where the emphasis has been on separating ^{13}C resonances on the basis of their multiplicity, i.e. the number of directly attached ^1H s. This type of information, when combined with the analysis of ^{13}C chemical shifts, is very often sufficient for determining the chemical structure of rather complex organic molecules. As such, spectral editing of solution NMR finds wide application in industry for the structural characterization of polymers, drugs, and petroleum based products. Development of similar methods which are applicable to solid samples has been motivated by a large number of important applications to geochemical and material science.

This article deals with spectral editing approaches developed specifically for high-resolution solid state NMR of ^{13}C . Many different strategies have been applied to this problem, and the space provided here unfortunately does not permit covering every aspect of this subfield. Most of the relevant literature is cited in two recent papers,^{1,2} and the interested reader may find more extensive citations contained therein.

2 BACKGROUND ON SPECTRAL EDITING OF LIQUIDS

The high information content of ^{13}C NMR spectra of liquids is well known. It follows directly from the large dispersion of the ^{13}C chemical shift and the remarkably tight correlation of ^{13}C chemical shifts with structure. The beautiful stick-spectrum simplicity of ^{13}C spectra is made possible by ^1H decoupling and the low natural abundance of ^{13}C which eliminates complications from ^{13}C – ^{13}C J couplings. Their information content is greatly increased if the multiplicity of the ^{13}C resonances can be determined.

Editing techniques for ^{13}C NMR of liquids rely on the fairly narrow range of values for $^1J(^{13}\text{C},^1\text{H})$. This permits one to devise pulse sequences in which the evolution of the ^{13}C magnetization can be made to depend principally upon the number n of directly attached ^1H s in CH_n groups. The attached proton test (APT) is the simplest example. In its most basic form, a $\pi/2$, τ , π , τ , acquire echo sequence is applied to the ^{13}C with ^1H decoupling during acquisition. A π pulse is also applied to the ^1H s after the first τ , resulting in J modulation of the ^{13}C spin echo. During the 2τ evolution period the dephasings of the ^{13}C chemical shifts are refocused, while those due to $^1J(^{13}\text{C},^1\text{H})$ accumulate. Setting τ to $\frac{1}{2}J$ produces a spectrum in which the CH_3 and CH_1 resonances are inverted, while the CH_2 and CH_0 resonances are absorptive.

For complex ^{13}C spectra, more powerful methods are required, but all rely upon J couplings in some manner. In editing protocols based on INEPT, J modulation is used to label the ^1H magnetization which is then transferred to the ^{13}C (see *INEPT*). The various CH_n groups can be amplitude modulated in distinct ways depending upon the length of the time evolution due to J coupling. On this basis schemes can be devised in which linear combinations of a few different experiments produce CH_3 -only, CH_2 -only, CH_1 -only, and CH_0 -only spectra. Techniques utilizing DEPT provide some improvement in selectivity, as the differentiation of CH_n groups depends upon a pulse flip angle rather than a period τ of free evolution under $^1J(^{13}\text{C},^1\text{H})$. Especially clean separation of CH_n subspectra has been achieved using multiple quantum coherence among the J -coupled spins. This subspectral editing using a multiple-quantum trap (SEMUT) has the advantage of being relatively insensitive to the value of $^1J(^{13}\text{C},^1\text{H})$.

3 CHALLENGES POSED BY SOLIDS

As discussed elsewhere in the Encyclopedia, obtaining high-resolution ^{13}C spectra of organic solids requires both magic angle spinning (MAS) and high-power decoupling of the protons. These techniques are usually combined with cross polarization (CP) in a CP MAS experiment. The need to remove broadening associated with chemical shift anisotropy and ^{13}C – ^1H dipolar couplings presents a new set of problems in the design of methods for spectral editing. Over the last 20 years of development in high-resolution NMR of solids three basic strategies have been applied to this problem. The first has been to design pulse sequences which produce J -modulated signals in solids, and thereby directly adapt the techniques just discussed to solids. The others use ^{13}C – ^1H dipolar couplings as the basis for selection of CH_n . Some of these methods use the relative strengths of dipolar couplings or rates of CP to differentiate ^{13}C signals of different multiplicities. Others rely upon the establishment of quasi-equilibrium states in the CP process and thus differentiate the ^{13}C multiplicities on the basis of the ratio of the inverse rotating frame spin temperature of the ^{13}C to that for its directly bonded protons.

3.1 J Modulation in Solids

Observing resolved $^1J(^{13}\text{C},^1\text{H})$ -coupled multiplets in CP MAS ^{13}C spectra of solids is made difficult by the strong

^1H – ^1H and ^1H – ^{13}C dipolar couplings. In the absence of strong on-resonance ^1H decoupling, CP MAS spectra of typical rigid samples are broad and relatively featureless. The ^1H – ^{13}C dipolar broadening is by itself inhomogeneous, and should therefore be suppressed by MAS. However the spin-exchange mediated by the ^1H – ^1H dipolar couplings is faster than typical rates of MAS. Therefore the spin states of ^1H can change several times during a MAS cycle, and the average of the ^1H – ^{13}C dipolar interaction is then no longer zero. In a simplified picture one can consider this to be a lifetime broadening of the ^{13}C resonances due to the short lifetime of the spin states of the directly attached protons. Terao and co-workers³ first demonstrated that suppression of the ^1H – ^1H dipolar couplings could make it possible to observe $^1J(^{13}\text{C},^1\text{H})$ -coupled multiplets in solids. In their work, ^1H decoupling at the magic angle in the rotating frame was first used. Subsequently a number of homonuclear sequences such as MREV-8 have been applied as homonuclear multiple pulse decoupling (MPD) for this purpose. For systems such as plastic crystals where molecular motion has already appreciably averaged the dipolar couplings, MPD produces CP MAS spectra with well-resolved $^1J(^{13}\text{C},^1\text{H})$ coupled multiplets. The couplings observed are reduced by the scaling factor appropriate to the particular MPD sequence used.

This approach has been extended to editing schemes that most resemble those used in liquids. The basic approach is to insert MPD sequences in the periods of free evolution under $^1J(^{13}\text{C},^1\text{H})$. APT-type spectra of motionally narrowed solids have been acquired in this fashion, but in the general case the MPD does not produce sufficient narrowing of the proton NMR spectra to permit sustained J modulation. Terao and co-workers⁴ have investigated the limitations of this approach most extensively for rigid solids. One sequence they have successfully used in producing J modulation for rigid solids consists of CP followed by a J -modulated rotor synchronized echo. During the first half of the echo, magnetization of the ^{13}C nuclei evolves under proton homonuclear decoupling. This period, t_1 , is adjusted to be equal to one rotor cycle. Over the course of the rotor period J modulation accumulates, but any modulation by the ^{13}C – ^1H dipolar coupling and the ^{13}C CSA is refocused. After the π pulse, high-power dipolar decoupling is applied for another period t_1 . This second interval refocuses the isotropic chemical shift and effects of any bulk susceptibility broadening that accumulated during the first t_1 period. FIDs taken as a function of t_1 then are largely only modulated by $^1J(^{13}\text{C},^1\text{H})$. In this manner a 2D heteronuclear J -resolved spectrum can be obtained with multiplets in the ω_1 dimension. However this approach still does not yield clean multiplets. For instance, the outer lines in quartets for CH_3 groups are very much broader than the central pair, and they are barely resolved.

At the moment, J modulation based editing techniques for solids will remain useful only for systems with significant motional narrowing. Advances in the efficiency of homonuclear decoupling, especially under conditions of MAS, are needed before such techniques can become widely applicable. Problems also remain in combining these homonuclear decoupling requirements with the typical hardware used for CP MAS NMR. While the approach has been proven in principle, development of generally applicable methods for solids along these lines remains a challenge for the future.

3.2 Dipolar Dephasing and Related Schemes

The most generally applicable editing techniques for solids take advantage of the strong dipolar couplings inherent in solids, rather than treating them as a nuisance to be eliminated. The simplest approach to spectral editing in CP MAS NMR of organic solids is the venerable technique⁵ of dipolar dephasing (DD) or interrupted decoupling. After CP, the ^1H decoupler is turned off for $\sim 50\ \mu\text{s}$. This is a sufficient time for the ^{13}C – ^1H dipolar coupling to dephase the transverse magnetization for any ^{13}C with a directly bonded ^1H , as long as the dipolar coupling is not motionally averaged. Therefore the lines for rigid CH_1 and CH_2 groups are effectively suppressed. Rapid rotation of CH_3 groups at room temperature leads to different behavior for these protonated carbons. This rotation renders the three ^{13}C – ^1H dipolar couplings equal, and reduces them to one-third of their static value. Depending upon the spin state of the protons, the ^{13}C in a CH_3 group can experience one of two possible dipolar fields. Whenever the three protons are in the same state ($\alpha\alpha\alpha$ or $\beta\beta\beta$), the three couplings reinforce one another, and the ^{13}C experiences the field of a single full ^{13}C – ^1H dipolar coupling. However, three-quarters of the time the ^1H s are in a state such as $\alpha\alpha\beta$ or $\beta\beta\alpha$. In this instance the fields due to two of the couplings will exactly cancel. The net dipolar field then is usually only one-third of a single ^{13}C – ^1H dipolar coupling, and this is similar to that often experienced through nonbonded contacts by a CH_0 . Thus, in most instances, methyl groups at room temperature behave like nonprotonated carbons under dipolar dephasing. The DD spectrum then consists of slightly attenuated resonances for just the CH_0 and CH_3 groups. Comparison with a fully polarized CP MAS spectrum provides a simple qualitative method for categorizing resonances as either $\text{CH}_3 + \text{CH}_0$ or $\text{CH}_2 + \text{CH}_1$. In many instances, a simple CP MAS spectrum can be fully assigned using this approach in combination with information from linewidth or chemical shifts.

Several approaches have been taken to improve on the basic DD technique. In some instances the dephasing interval leads to an unacceptable linear phase correction due to the delayed acquisition. A π pulse may be inserted in the interrupted decoupling interval to alleviate this to some degree. However, as first pointed out by Munowitz and Griffin,⁶ the π pulse should be applied only after a full rotor period to ensure that both the isotropic and anisotropic portions of the ^{13}C chemical shift are refocused. Other groups have investigated the spin dynamics of the DD experiment with the desire to separate CH_n resonances more completely or quantitatively.⁷ The approach has been to fit the dephasing of the ^{13}C resonances as a function of the dephasing time, τ_D , to some type of model dephasing function. Since it can be argued the different CH_n groups may have characteristic dephasing characteristics, this approach would seem to have some validity. In this manner one can then extrapolate back in dephasing time to recover the initial intensities of the CH_3 and CH_0 resonances.

The best way to view the DD experiment is actually as a low-resolution 1D version of separated local field (SLF) spectroscopy under MAS conditions. During τ_D the ^{13}C FID is dominated by the ^{13}C – ^1H dipolar couplings, and is damped by the ^1H – ^1H dipolar interactions. An isolated CH_1 group then has a decay profile that is essentially a damped Pake doublet FID, that for a CH_2 , i.e. a Pake ‘triplet’. Since the local structure of isolated CH_n groups of a given n does not

vary appreciably in organic solids, these decays would be quite characteristic were it not for the ^1H – ^1H dipolar couplings. This complication can be removed by applying MPD during the dephasing interval. In this manner the number of dipolar couplings is determined from a spectral pattern, i.e. sideband intensities, rather than from a less structure-specific average dephasing rate.

The first proposal for this type of MAS SLF spectroscopy was by Munowitz and Griffin⁶ as a means of measuring C–H distances. Webb and the author⁸ later investigated using the spinning sideband patterns characteristic of the different CH_n groups for spectral editing. The proposed 2D experiment consists of CP followed by MPD (usually MREV-8) for t_1 to produce dipolar evolution in the first frequency dimension. This is followed by a $\pi/2(\phi_i)$, τ , $\pi/2(x)$ sequence to selectively project the ^{13}C magnetization onto one axis of the rotating frame. The period, τ , is a few hundred μs and is used to dephase magnetization not placed along z by the $\pi/2(\phi_i)$ pulse. Following the $\pi/2(x)$ pulse, the normal dipolar decoupled ^{13}C FID is acquired during time period t_2 . Cycling the phase ϕ_i in a time proportional phase incrementation scheme avoids the need to acquire a quadrature data set in t_1 . The sideband patterns generated this way in the ω_1 dimension retain both dipolar and CSA effects. However, at low-to-moderate field strengths the patterns are so dominated by the ^{13}C – ^1H dipolar couplings that they can still be easily deconvolved into their CH_n components. Since CH_2 groups have two dipolar couplings, they have nearly twice as many sidebands, and are readily distinguished from CH_1 groups by this technique. Decomposition of complex CP MAS spectra with many overlapping lines has been demonstrated using this approach. At higher fields the same deconvolution methods can be applied using Munowitz and Griffin's rotor-synchronized sequence to eliminate the complications due to CSA. The requirement for delaying acquisition to several rotor periods after the initial CP interval, however, can result in substantial losses in sensitivity. A further simplification has been proposed by Sethi.⁹ Since the temporal evolution during t_1 in the MAS SLF experiments is well understood, only a few special times t_1 need be acquired. Using this approach Sethi has introduced 1D editing schemes that also can be used to separate CH_1 and CH_2 resonances.

3.3 Schemes Using CP Dynamics

The previous methods rely upon the relative strengths of ^{13}C – ^1H dipolar couplings or the different numbers of dipolar couplings to discriminate between different CH_n groups. The dipolar couplings are used essentially to dephase or modulate the ^{13}C resonances in a predictable manner. Another strategy is to use the ways in which these differences in the dipolar coupling network result in differences in the CP dynamics between the CH_n groups.

The simplest description of the CP process considers the transfer as a first-order kinetic process with a time constant T_{CH} . However, it is well known that this description is only qualitatively correct, and only phenomenologically describes the long-time behavior ($t \gg T_2$). At short CP times the Hartmann–Hahn transfer is dominated by the details of the dipolar coupling network between a ^{13}C and its directly bonded ^1H s. In single crystals, one even observes transient

oscillations in the polarization transfer. For powdered samples under moderate MAS, the transient effect manifests itself as a rapid initial period of CP transfer in which the ^{13}C and its attached ^1H s come into a quasi-equilibrium. Spin diffusion to the more distant protons transports polarization more slowly to these ^1H s coupled to the ^{13}C . This slower process determines the rate at which the ^{13}C reaches its final fully polarized state. In the quasi-equilibrium state, the initially unpolarized ^{13}C nuclei share the polarization equally with their directly attached protons. CH_1 and CH_2 groups then polarize to one-half and two-thirds of their full intensity, respectively, on the short timescale. Because of their motionally averaged dipolar field, CH_3 groups behave similarly to nonprotonated carbons. Both the CH_0 and CH_3 groups then polarize more slowly, with the polarization bottleneck to full enhancement usually being the rate of ^1H – ^1H spin diffusion. As long as the transfer of transient polarization among the closely coupled spins is faster than the ^1H – ^1H spin diffusion and direct transfer from more distant protons, it can be put to good use in spectral editing schemes.

One particularly useful approach for distinguishing the signals of $\text{CH}_1 + \text{CH}_2$ from those of $\text{CH}_0 + \text{CH}_3$ based on the previous ideas is the depolarization (DEP) technique.¹⁰ After a several ms CP interval, the spin locked ^1H magnetization is allowed to dephase by turning off the ^1H rf for several hundred μs , while keeping the ^{13}C spin locked. Turning the ^1H rf back on reestablishes the CP contact, and the ^{13}C magnetization can be used to repolarize the depolarized ^1H s. If the phase of the ^1H rf is switched 90° every 25–50 μs over a total period of a few hundred μs , there will be no net buildup in the ^1H magnetization, only a net drain from the ^{13}C . Since only the $\text{CH}_1 + \text{CH}_2$ carbons polarize on this timescale, their signals are fully depleted after the depolarization, while the $\text{CH}_0 + \text{CH}_3$ signals are attenuated only slightly. The resulting DEP spectrum is much like a DD spectrum. However since the ^{13}C are spin locked until the depolarization is finished, there are no problems with linear phase errors as in DD.

Polarization inversion (PI) can also be used in a similar fashion.¹¹ In this technique the ^{13}C are first fully polarized by CP, and the phase of the rf in the ^1H channel suddenly inverted. Since the ^1H spin temperature has now been inverted, the ^{13}C will try to follow. Those ^{13}C with strong ^{13}C – ^1H dipolar couplings first quickly depolarize, and then repolarize in the opposite direction. Since the zero crossings for CH_1 and CH_2 groups are different, they can be used in some instances to distinguish resonances. Nulling of resonances in this manner has also been referred to as cross depolarization¹² (CPD). A further variant adds a final short polarization period onto the CPD sequence.¹³ The depolarization and repolarization periods in this cross-depolarization–repolarization technique (CPDR) can be adjusted so as simultaneously to null the CH_1 and CH_2 groups. This is not in general possible with the cross-depolarization interval alone.

Sangill et al.² have presented a thorough study of the use of CPD and CPDR in spectral editing. Their analysis focused on using optimized combinations of CPD and CPDR spectra to produce CH_n -only spectra, $n = 0$ –3, while maintaining good sensitivity. By paying careful attention to the CP dynamics, they were able successfully to separate complex CP MAS spectra into their CH_n subspectral components.

Burum and Bielecki¹⁴ have introduced a particularly clever method based on CP dynamics for selectively detecting CH_2

groups in CP MAS NMR. Their method, WIMSE (windowless isotropic mixing for spectral editing), starts with a CP interval under a multiple pulse cycle which eliminates the ^1H – ^1H dipolar couplings during the CP step while maintaining the ^{13}C – ^1H couplings. Over a MAS rotor period under these conditions, no net polarization is transferred to ^{13}C nuclei in CH groups. Instead, whatever magnetization is transferred at the start of the rotor cycle ‘echoes’ back from the ^{13}C to the ^1H at the end. However, the presence of two dipolar couplings in a CH_2 group defeats this ‘rotational polarization echo’ effect. The resulting spectrum then consists solely of the CH_2 component in a complex CP MAS spectrum. CH_3 and CH_0 lines do not appear as their CP rates are too slow.

3.4 Techniques Using Quasi-Equilibrium States

Another successful method based on differences in CP dynamics between the different CH_n groups is the solid state attached proton test, or SSAPT method. Initially the ^{13}C are fully polarized using a 2–3 ms CP interval. Immediately following this, a short PI period is applied, typically on the order of $50\ \mu\text{s}$. At the beginning of the PI time the ^{13}C and their directly attached ^1H s are equally polarized. Upon reversal of the phase in the ^1H spin locking rf, this equilibrium is broken, and the spins try to reequilibrate. Since the CH_3 and CH_0 groups polarize slowly, they are relatively unaffected by this short PI interval. The CH_2 and CH_1 groups, on the other hand, have sufficient time to reach a quasi-equilibrium state through a rapid transient CP transfer. In the case of the CH_1 group, the ^{13}C and the ^1H have equal but opposite polarizations at the start of the PI. During the short PI time these magnetizations cancel, and the signal for the CH_1 carbons is very effectively nulled. The ^{13}C nuclei in the CH_2 groups carry 1 unit of polarization as opposed to the -2 units in the ^1H s at the beginning of the PI interval. This results in -1 unit of total polarization to be shared among the three spins in the quasi-equilibrium state. At the end of the PI period, the CH_2 signal is then inverted with an intensity of $-\frac{1}{3}$ of its fully polarized signal. The SSAPT spectrum then has $\text{CH}_3 + \text{CH}_0$ signals nearly fully polarized and positive, CH signals nulled, and CH_2 signals inverted at one-third intensity. In many instances this provides a very straightforward means of separating the contributions from the different CH_n groups to a ^{13}C CP MAS spectrum.^{15,16}

This approach has been extended to a complete spectral editing protocol by Wu, Burns, and the author.¹ Since the establishment of the quasi-equilibrium state depends upon the ratio of the inverse rotating frame spin temperatures of the ^{13}C and its directly bonded ^1H s, this technique is less sensitive to the CP rates. In this sense it is a relatively robust editing procedure.

The complete spectral editing procedure due to Wu et al. uses four basic experiments (see Figure 1). One begins by acquiring a CH_2 -only spectrum. The sequence used starts with a short CP contact which polarizes the CH and CH_2 groups to their quasi-equilibrium intensities of $\frac{1}{2}$ and $\frac{2}{3}$ respectively. This is followed by a short PI interval of roughly the same length. During PI the CH signals null, as does any small CH_3 or CH_0 polarization built up during the CP step. The CH_2 ^{13}C magnetization goes to $-\frac{1}{3}$ of its initial value, resulting in a spectrum with $-\frac{2}{9}$ the intensity for these carbons. This

Figure 1 Sequences used in the editing protocol of Wu et al. All employ simultaneous phase inversion to alleviate problems with Hartmann–Hahn mismatches. (a) CP sequence. The additional spin locking delay τ_{SL}^S is used to make the total ^{13}C spin locking time the same in all of the sequences. (b) SCPPI sequence used to acquire CH_2 -only spectra. (c) Depolarization sequence. The time τ_{SL}^I is added in these sequences mainly to minimize distortions from ^1H rotating frame relaxation

short CP polarization inversion (SCPPI) spectrum then has contributions from only the CH_2 groups.

The second experiment is a short contact CP (SCP). This will have intensity principally from the CH and CH_2 carbons. Another short CP spectrum with a depolarization interval is also acquired (SCPD). The SCPD spectrum can be used to subtract out the contamination of the SCP data from CH_3 and CH_0 groups. Unfortunately the CH_3 and CH_0 carbons have sufficiently different CP dynamics that they are differentially attenuated, and this subtraction alone is insufficient. In most instances, however, the shift ranges for CH_3 and CH_0 groups are adequately separated so that a dividing line on the ^{13}C chemical shift scale can be chosen to separate these groups. Different weighting factors can then be applied to the upfield (CH_3) and downfield (CH_0) regions for this purpose. The result of this procedure is a relatively clean CH-only spectrum.

To acquire semiquantitatively correct CH_0 and CH_3 spectra, a long CP depolarization spectrum is acquired (LCPD). This spectrum is again split into CH_0 and CH_3 regions, and each part corrected for the differential signal loss of the two types of groups in the depolarization step.

The cleanest and most quantitative results are obtained with this method if the intensity factors for spectral decomposition are determined experimentally on a known model system.

Table 1 Typical Intensities for CH_n Resonances in Pulse Sequences Used for Spectral Editing

Experiment	CH_n			
	CH_0	CH_1	CH_2	CH_3
LCP	100	100	100	100
SCP	10.5	57.5	68	22.6
SCPPI	0	0	-22	0
SCPD	7.2	0	0	10.4
LCPD	82.5	0	0	57.5

Using the set of sequences shown in Figure 1, the intensity matrix in Table 1 is found to be typical. LCP is used to denote a standard (long) CP experiment which is used as the 100% intensity reference.

As the entries demonstrate, the CH and CH_2 group intensities in the SCPPI and SCP experiments are quite close to those expected from the quasi-equilibrium description of the CP dynamics.

Figure 2 compares the four spectra acquired in the editing protocol for cholesteryl acetate to the normal CP MAS spectrum. In the solid state there are two molecules in the unit cell producing a doubling of the lines. Furthermore, changes in conformation lead to significant shifts in many resonances. Using the intensity matrix in Table 1, the CH_n , $n = 0-3$, only spectra can be reconstructed from these data. The results of this data manipulation are shown in Figure 3, clearly demonstrating the simplifications made possible by this spectral editing approach. As a check on this editing protocol, one may sum the CH_n subspectra to produce a synthetic CP MAS spectrum. This is compared with the normal CP MAS

**Figure 2** Data from a spectral editing experiment on cholesteryl acetate. (a) Normal CP spectrum for comparison. (b) SCP spectrum. (c) SCPPI spectrum. (d) SCPD spectrum. (e) LCPD spectrum. In practice larger numbers of scans are acquired for the lower signal-to-noise experiments as indicated in the figure**Figure 3** Subspectra constructed from the data in Figure 2. (a) Normal CP MAS spectrum again for comparison. (b) CH_0 -only. (c) CH_1 -only. (d) CH_2 -only. (e) CH_3 -only. Some of the assignments made possible by the editing technique are given in the inset

spectrum in Figure 4, along with the difference of the two. The small differences observed indicate the reliability of the approach used.

4 EXPERIMENTAL CONSIDERATIONS AND CAVEATS

Except for the simplest approaches to spectral editing in solids, one must pay some extra attention to the experimental setup. In particular, very high MAS spin rates and rf inhomogeneity can adversely affect the CP dynamics relied upon in most methods. The sharpening of the Hartmann-Hahn condition, and the need to match typically on a sideband condition, $\omega_1 = \omega_2 + \omega_r$, makes a homogeneous rf field more important than in a standard CP MAS experiment. Good experimental practice requires stable rf levels, restricting the sample to well within the rf coil, and a stable spin rate. For experiments utilizing short CP, PI, or depolarization periods, additional modifications that make the matching condition less sensitive are needed. Our group has found the simultaneous phase inversion method^{1,14,15} easy to incorporate in editing schemes. The pulse sequences in Figure 1 utilize this approach to make the results much less sensitive to how well the matching condition is set and maintained throughout the experiment.

Figure 4 Comparison of the (a) normal CP MAS spectrum and (b) the synthetic one produced by direct summation of the subspectra in Figure 3(b)–(e). (c) The difference between the normal and synthetic CP MAS spectra

When spectra are to be combined in an editing procedure, it is also important to consider rf heating, droop in the rf levels, and $T_{1\rho}$ relaxation. Whenever possible, it is a good practice then to keep the rf fields on for comparable periods of time in the different experiments to be combined. The sequences in Figure 1 have been constructed to take these additional complications into account. Table 2 gives the set of delays in reference to Figure 1 that have been found to give optimal performance in editing applications on rigid solids at moderate fields and MAS rates. These parameters have been used and tested in applications to many coals and polymers as well as on model systems.

Methods which employ homonuclear decoupling sequences require additional care in spectrometer alignment. For these methods one must more carefully adjust all rf levels, and pay especial attention to rf homogeneity. In practice one must follow the same procedures as used to prepare for a ^1H CRAMPS experiment. Similar complications from the interaction of the MAS and the MPD also occur as found in CRAMPS.

The majority of the methods that have been discussed here rely on differences in the dipolar coupling networks found between the various CH_n groups. These are washed out when there is significant motional averaging, and as such

all of these methods have limitations. On the other hand, such motional narrowing has many signatures which are easy to recognize, and provides another means of discriminating between resonances in a complex spectrum. When very fast MAS rates are employed, the spin dynamics also change.¹⁷ Most methods presented here work best at low to moderate MAS rates (5 kHz or below). Additional complications can arise at high fields because of the CSA spinning sidebands. Since different molecular orientations with respect to the rotor contribute more intensity to some sidebands than others, the inhomogeneous nature of the CP dynamics can be accentuated. Under many editing schemes the center and sidebands can then behave differently, complicating analysis. In the light of these difficulties, most applications to complex systems have employed low field operation ($B_0 < 4\text{ T}$). Additional work is needed to delineate how high-field and high-speed MAS operation can be accommodated with the majority of these methods.

5 SUMMARY

At present there are many methods available for distinguishing $\text{CH}_3 + \text{CH}_0$ groups from CH and CH_2 centers in CP MAS spectra. A number of reliable approaches for separating CH and CH_2 groups have also appeared, and some of these have been combined in complete spectral editing protocols which separate resonances by multiplicity. These methods have many applications in organic geochemistry and polymer science. Further advances are required before most of these techniques can be combined with operation at the highest available field strengths and spin rates.

Acknowledgments

I wish to acknowledge the especially important contributions of two of my colleagues in this field. The first is Dr Gretchen Webb, my first graduate student, who was instrumental in working out 2D MAS SLF methods for editing, as well as developing much of the hardware that

still makes these experiments work so well in our laboratory. The second is Dr Xiaoling Wu, my long-time associate, collaborator, and friend. It is because of Xiaoling's experimental acumen and theoretical insight that our laboratory has been able to contribute so successfully to the development of spectral editing methods for solids.

1 INTRODUCTION

Stereochemistry (from the Greek *stereos*, meaning ‘solid’), the three-dimensional architecture of molecules at the atomic level, underlies our world of appearances, from the grit of grains of sand to the intricacies of an infant’s hand. It is a tenet that the macroscopic properties of solids are a consequence of this architecture. It is also thought that the myriad of chemical transformations depends in a subtle way on stereochemistry; the living cell, a microscopic center for the chemical reactions essential to life, depends on stereochemistry for the ‘recognition’ of one molecule by another during the initiation of reactions which, in turn, produce molecules whose biological utility again has an exquisite dependence on their architecture. Such are the working hypotheses at the root of an enormous effort to establish the stereochemistry of animate and inanimate materials.

NMR is playing an important role in this quest—witness the ubiquity of NMR spectrometers in chemical laboratories. One stereosensitive property of a molecule is the scalar interaction between magnetic nuclei nJ , in which n represents the number of intervening chemical bonds; n can run from unity, in all molecules, to at least 14 in some molecules (see *Indirect Coupling: Theory and Applications in Organic Chemistry*). For $n \geq 4$, nJ is often relatively small. As the resolution of NMR spectra improved, the presence of such long range coupling constants became clear and their relationship to stereochemistry became a subject of study. Among the earliest theoretical and experimental investigators of this topic were F. A. L. Anet, M. Barfield, A. A. Bothner-By, D. M. Grant, H. Günther, R. A. Hoffman, H. S. Gutowsky, G. J. Karabatsos, M. Karplus, J. Meinwald, and H. M. McConnell. Barfield has been particularly active over a long period in providing theoretical stimulation to experimentalists. A number of extensive reviews^{1–8} of the theory of long range coupling constants and their stereochemical applications are recommended.

The aim of this article is to provide an overview of the utility of long range coupling constants in stereochemical analysis.

A very brief discussion is given of stereochemical concepts, followed by a heuristic description of the origins of nJ , which is elaborated by specific examples drawn mainly from organic chemistry. This choice is dictated by the available space and is also colored by personal taste. Apologies are in order to those authors whose work may well have been cited. Only a few of the thousands of long range coupling constants can be included; even if only the more familiar NMR-active nuclei (^1H , ^{13}C , ^{19}F , and ^{31}P) were included for $4 \leq n \leq 12$, then the variety of chemical bonding patterns would require a substantial book for an adequate discussion.

2 STEREOCHEMISTRY

The electrons in a molecule move with speeds near a million meters per second and therefore traverse the space of a moderately sized molecule about a thousand million million times in one second. In so doing, the electrons tie the very small but relatively massive nuclei into a floppy, pulsating, rotating object, which is stable at ambient temperatures. At certain distances between the nuclei, the Coulombic forces of attraction between the nuclei and electrons outweigh those of repulsion between nuclei and between electrons. For nearest-neighbor nuclei these distances are called ‘bond lengths’; intuition is correct in suggesting that the electrons tend to concentrate in the regions between neighboring nuclei. If two electrons undergo this concentration one has a single bond, if four, a double bond, and so forth.

The diversity of molecular size and shape is breathtaking. The diatomic oxygen molecule, so necessary to our very existence, contains two nuclei and sixteen electrons. A small diamond, also thought necessary by some, is a single molecule containing some 10^{22} nuclei and six times as many electrons. When diamond burns in oxygen, one obtains the linear, triatomic molecule, carbon dioxide, which is considered obnoxious, yet is essential for photosynthesis. One of the aims of modern experimental and theoretical chemistry is the elucidation of the detailed shapes of these various three-dimensional objects, i.e. their stereochemistry.

Consider a tetra-atomic molecule ABCD. In (1), the four different nuclei are connected in a unique way: A is attached to B by a single bond and not to C, and so forth. This connection scheme defines the *connectivity* or *constitution* of the molecule and represents the first step in the stereochemical description. The angles between the internuclear vectors, A–B and B–C, for example, are called ‘bond angles’. An important angle θ , the torsion or dihedral angle between the two planes containing ABC and BCD, defines the *configuration* or the *conformation* of the molecule. If a very large energy input is needed to interconvert (1) and (3), i.e. if the thermal kinetic energy (motion of the molecules through space may lead to a collision in which one molecule receives energy from another) is small compared to the energy needed to twist (1) into (3), or vice versa, then one may speak of two configurations of the molecule, or of *configurational isomers*. If you have configuration (1) and, some time later, say days, (1) has not turned even partially into (3), even under heat, then you may speak of configuration. Often, such a situation requires a double bond between C and D, indicated by two strokes (double bond), and one refers to ‘breaking the double bond’ during configurational isomerization. If the energy needed

to interconvert (1) and (3) is not large compared to the thermal energies, then the sample of the substance ABCD may well contain appreciable amounts of (1) to (3). One has an equilibrium among conformational isomers or *conformers*. The relative amounts, or populations, of the conformers usually change as the temperature changes.

The two terms 'configuration' and 'conformation' relate to the human timescale. Near absolute zero in temperature, there would be little need for both terms; one would suffice in most instances. It all depends on the flexibility or floppiness of the molecule. A certain care is therefore needed in the description of the stereochemistry of a molecule. If the energy barrier to interconversion among (1) to (3) is small, then ABCD takes on all conformations, defined by θ , with similar probabilities. All angles from 0° to 180° are then significantly represented in the sample (ensemble). A molecule's reactivity, how it combines with other molecules to form one or more product molecules, and how rapidly it does so, can depend strongly on its conformation/configuration; this is one reason for the study of stereochemistry.

A complete stereochemical description requires precise values of bond lengths and bond and torsion angles, preferably with a potential function describing the energy of a molecule as a function of θ . Furthermore, because the molecule vibrates (pulsates), a knowledge of all the other vibrational motions, such as bond stretches and bond angle deformations, together with their frequencies and amplitudes, is desirable. Finally, a map of the electron density, at least up to distances of 10^{-9} m from the molecular periphery, is also needed.

Needless to say, a variety of experimental and theoretical techniques is necessary for these purposes. Most techniques utilize the fact that rotational, vibrational and electronic energies of molecules are quantized and directly related to the stereochemical properties. The energies, or at least their differences, can be ascertained by stimulating transitions between the various states of different energies with the photons available from electromagnetic radiation. Other methods scatter the photons from the molecule in the gas or solid and, from interference patterns formed by the scattered photons, deduce electron densities and, by inference, the sites of the nuclei.

NMR techniques, by way of contrast, use the magnetic properties of nuclei and their magnetic interactions with other nuclei and/or electrons to deduce molecular stereochemistry. The magnetic interactions between the nuclei and electrons in

molecules are about a million times smaller than the electrostatic interactions which actually determine the stereochemistry. Therefore, at first sight it appears unreasonable to focus on the magnetic interactions as a source of stereochemical information. After all, the magnetic dipole moment of the nucleus is only weakly coupled to the very forces which mould the molecular shape. Paradoxically, it is this fact which allows NMR to be perhaps the single most general tool for stereochemical analysis. The magnetic field B_0 of the NMR spectrometer penetrates the molecular space almost unaltered and orients the magnet moment of the nucleus into certain definite directions. Under certain conditions the magnetic interactions between the nuclei and between the nuclei and the electrons appear as perturbations of the interaction between B_0 and the nuclei. As a consequence, the NMR spectrum, whose basic frequency represents the B_0 /nucleus energy, is somewhat shifted and split into a number of peaks or frequencies. These shifts and splittings, the latter being related to the J values, can be interpreted in terms of stereochemistry.

3 THE COUPLING CONSTANT BETWEEN NUCLEI

The scalar spin-spin interaction energy between two nuclei is represented by $h\hat{I}_i \cdot \hat{I}_j$, where $\hat{I}_i$ is the spin angular momentum vector operator of nucleus i . Because the magnetic moment μ is proportional to $\hat{I}$, J is also proportional to the product of the two nuclear moments (see *Nuclear Spin Properties and Notation*). In this article, J is given in units of hertz. The dot, or scalar, product in the expression above applies to molecules in the isotropic liquid or gaseous states. It depends on the relative orientations of the two spins, not on their positions in space. Therefore J is unchanged by molecular reorientations, unlike the dipolar interactions which average to zero during such reorientations (see *Dipolar and Indirect Coupling Tensors in Solids*). The directions of the nuclear spins are only very slightly coupled to the orientation of the molecule in space, but are coupled to B_0 . The scalar interaction modifies this latter coupling by definite amounts, proportional to J , and hence appears in the fine structure of the NMR spectrum. Figure 1 shows the ^1H NMR spectrum of the methyl protons of 1-phenylpropyne (4). In the absence of J only a single peak would occur; instead there exist many peaks arising from $^{6,7,8}J$, long range proton-proton coupling constants, over six, seven and eight formal bonds ($n = 6, 7, 8$). The long range coupling constants can be extracted by standard procedures (see *Analysis of High-Resolution Solution State Spectra*).

How does J come about? Consider a hydrogen atom. In addition to the electrostatic attraction between the electron and the proton, an energy of 13.6 eV, there exists a magnetic interaction of 6.0×10^{-6} eV (the hyperfine interaction, that is, very small), which aligns the spins of the proton and

Figure 1 The ^1H NMR spectrum at 300 MHz of the methyl protons of 1-phenylpropyne ($\text{C}_6\text{H}_5\text{C}\equiv\text{CCH}_3$) as a dilute solution in acetone- d_6 at 300 K, has a linewidth at halfheight of somewhat less than 0.03 Hz. The upper, theoretical, spectrum comes from a precise spectral analysis and has the long range coupling constants $^6J(\text{H},\text{CH}_3)$, $^7J(\text{H},\text{CH}_3)$, and $^8J(\text{H},\text{CH}_3)$ of $-0.298(1)$, $0.145(1)$, and $-0.254(1)$ Hz, respectively. (Reproduced with permission of The National Research Council of Canada from T. Schaefer, R. Sebastian, and R. W. Schurko, *Can. J. Chem.*, 1992, **70**, 2365)

electron in an antiparallel fashion, as in (5). Mutual flips of these alignments give rise to radiation at 1420 MHz which is detectable in radioastronomy, exemplifying the underlying unity of the natural sciences. The hyperfine interaction operates when the electron is very near the proton (the contact interaction).

(5)

3.1 A Model of 1J

Now consider the hydrogen molecule (6). Because the electrostatic energies ensure the antiparallel spin alignment of the two electrons (paired off, singlet state), a consequence of the quantum properties of small particles, the contact interaction favors the overall spin orientations shown in (6). The nuclear spin is said to 'spin polarize' the electrons in the sense that—although the net electron spin in the bond, 'down' minus 'up', is zero when averaged over the space of the bond—at the left of the bond in (6) there occurs more 'down' than 'up' spin, and vice versa on the right. The net

result is that an antiparallel arrangement, defining a positive J , of the proton spins (crossed arrows) is favored by about 10^{-12} eV. This magnetic energy is tiny compared with the electrostatic energies yet, paradoxically, is easily measured by NMR. In the hydrogen molecule, J is 280 Hz or 1.1×10^{-3} kJ mol $^{-1}$, which is miniscule compared with the bond energy of 460 kJ mol $^{-1}$. It is clear that J , transmitted via the electrons, is proportional, at each end of the coupling path, to the size of the magnetic moment of the nucleus and, therefore, to the product of the two nuclear magnetic moments.

(6)

J is a second-order property of the molecule in the sense that it results from the product of two first-order interactions; here, two contact interactions. In another sense, because that contact interaction perturbs the ground state molecular wavefunction, the theoretical computation of J must take this perturbation into account; it does so by mixing electronically excited states into the ground state in a complicated fashion. Hence the quantitative computation of J from first principles is not easy (see *Indirect Coupling: Theory and Applications in Organic Chemistry*). In the present article, qualitative models of nJ , $n \geq 4$, which nevertheless can be made semiquantitative, are used to illustrate its stereochemical applications. As will be seen, the torsional dependence of J can sometimes be ascertained by empirical methods which allow rather precise stereochemical conclusions.

3.2 Models of 2J and 3J

In (7), a pair of protons separated by two formal bonds, as in a CH_2 fragment of a molecule, is indicated to have a negative 2J . The coupling mechanism favors a parallel orientation of the proton spin vectors. This is so because the two electrons, in different bonds but near carbon, have a lower electrostatic energy if their spins are parallel than if they are antiparallel. The lower energy, an illustration of Hund's rule, is probably a consequence of the fact that these two electrons move in such a way that they are attracted more strongly by the carbon nucleus when their spins are parallel—the spin serves as a sort of traffic policeman, one electron tending not to get between the other electron and the nucleus. The picture in (7) is called the 'Dirac vector model' of 2J , predicting a negative value, for example, in methane, where 2J is indeed -12.4 Hz. However, $^2J(\text{H},\text{H})$ is positive in some molecules. This failure of the model is shared by another kind of model, which is now illustrated for 3J .

(7)

The HCCH or ethanic fragment in (8) is the prototype of an important class of vicinal or 3J interactions (*Vicinal Coupling Constants and Conformation of Biomolecules*). The Dirac vector model correctly predicts a positive 3J , but it cannot account for its dependence on the torsion angle θ in (9). In fact, it is a direct interaction (not a dipolar interaction, which is also sometimes called 'direct') between the electrons in the two C–H bonds which is important in correlating the electron, and hence the proton, spins. The direct interaction, proportional to valence bond exchange integrals, is minimal when the two C–H bonds lie in mutually perpendicular planes ($\theta = 90^\circ$). An acquaintance with trigonometry, together with the constraint that 3J be positive, suggests that the θ dependence between 0° and 180° is mainly on $\cos^2 \theta$, and perhaps slightly on $\cos \theta$. This is indeed true. The stereochemical significance is obvious. Note that the 'through bond' mechanism, as in (8), is relatively unimportant.

This manner of argument implies that geminal spin correlations, as in (7), could combine with vicinal spin correlations, as in (9), to yield long range coupling constants nJ ($n \geq 4$) in larger molecular fragments and is therefore related to their geometrically extended stereochemistry. This is also true. One drawback concerns the magnitude of long range coupling constants. Generally speaking, for saturated fragments (single bonds) the magnitude decreases as n increases, simply because nJ arises either from the product of small interactions of the kind shown in (8) and (9), or because the direct interaction between bonds decreases with their separation; the bond exchange integrals (interactions) giving rise to spin correlation between electrons in different bonds depend on interelectronic distances in these structures. In (9), 3J is of the order of 10 Hz at $\theta = 0^\circ$ or 180° , whereas 4J has a magnitude of about 1 Hz in the propanic fragment below. Note that at least some deviation from perfect pairing is necessary for a finite J . However, for unsaturated molecules, in which extensive electron delocalization occurs, nJ can be sizeable and does not necessarily drop off monotonically as n increases. As an extreme example, $^{10}J(\text{F},\text{F})$ in (10) is 0.2 Hz in magnitude.

4 nJ ($n \geq 4$) IN SATURATED MOLECULES

In the propanic fragment (11) to (14), direct and indirect mechanisms can contribute to $^4J(\text{H},\text{H})$. The direct mechanisms are important¹¹ in conformations (12) and (13). In (12), the two C–H bonds are proximate in space and $1 \rightarrow 3$ interactions are important. Coupling constants arising in this way are often called 'through space', which is a misnomer because the molecule itself is largely empty space; perhaps, 'proximate' nJ would be a better name. In (13), an all-*trans* or zig-zag conformer, there is a direct interaction between the orbitals on the carbon atoms (rear lobes) to which the coupled protons are bonded, resulting in a relatively large positive $^4J(\text{H},\text{H})$. Indirect mechanisms are associated with $1 \rightarrow 2'' \rightarrow 3$ and $1 \rightarrow 2''' \rightarrow 3$, vicinal–vicinal, and with $1 \rightarrow 2 \rightarrow 3$ or $1 \rightarrow 2' \rightarrow 3$, geminal–vicinal, interactions in (11); the latter are difficult to evaluate. The indirect mechanisms can contribute to $^4J(\text{H},\text{H})$ with either sign, so that $^4J(\text{H},\text{H})$ can be positive or negative,¹¹ depending on the dihedral angles θ and $z\theta'$. In (14), the value of $^4J(\text{H},\text{CH}_3)$ is large, corresponding to $\theta = 180^\circ$.

A recent analysis (Schaefer et al., 1993) of the ^1H NMR spectrum of 2-phenyl-1,3-dithiane, (15), illustrates the stereochemical dependence of $^4J(\text{H},\text{H})$. The approximate torsion (dihedral) angles are given in (15). Note the positive shift of $^4J(\text{H},\text{H})$ as HCSC₂H, containing the heteroatom, sulfur, replaces the propanic fragment. A heteroatom attached to the propanic fragment can also alter 4J . Such substituent perturbations complicate stereochemical assignments and present challenges to the theorist [in fact, the positive shift noted for (15) can be reproduced with the INDO MO FPT formalism,¹² which takes a number of coupling mechanisms into account]. In principle, $^4J(\text{H},\text{H})$ is useful in the stereochemical analysis of other six-membered alicyclic rings which can occur in sugars and steroids, for example. Another example is provided¹³ by the five-membered ring in the anhydronucleoside (16). The signs and magnitudes of $^4J(\text{H},\text{H})$ are related to torsion angles¹⁴ in the furanose ring. Also, coupling constants over five bonds exist between H-1' and the methylene protons in (16).

As the molecular mass increases, the ^1H NMR spectra become very complex and the peak widths also increase due to unresolved long range coupling constants and to shorter relaxation times. Nevertheless, the presence of $^4J(\text{P},\text{H})$, as in the nucleotide (17) and whose magnitude is determined¹⁵ by the geometry of the P–O–C-5'–C-4' fragment, allows¹⁵ the assessment of $^3J(\text{H}-4',\text{H}-5')$ and $^3J(\text{H}-4',\text{H}-5'')$ in a double-helical dodecanucleotide (a DNA fragment). The vicinal coupling constants help in fixing the torsion angle in the fragment O–C-5'–C-4'–C-3'.

In rigid bicyclic systems,⁵ extended or multiple, all-*trans*, coupling pathways can exist, so that $^{4,5,6}J(\text{H,H})$ can be large [propanic (11), butanic, and pentanic paths]. Furthermore, C–H, F–H, P–H, F–F, Tl–H, and C–C long range couplings are known in such molecules; some of these are large for conformations analogous¹⁶ to (12) (proximate couplings). Many are tens of hertz in magnitude, or even as large¹⁷ as 820 Hz as in (18), a norbornane derivative; the electron density at the thallium nucleus is very large for this nucleus of atomic number 81.

5 nJ ($n \geq 4$) IN UNSATURATED MOLECULES

5.1 Alkenes and Acetylenes: σ, π Model

In unsaturated molecules such as alkenes and acetylenes the valence electrons are usually considered to be of two different types: σ and π electrons. Thus, in planar ethylene (19), the double bond between the carbon atoms is thought of as a single

σ bond and a single π bond; the latter is formed from electrons in p orbitals on the carbon atoms and yields maximum electron density above and below the plane of the molecule (the six nuclei lie in a plane in the most stable state of the molecule). This σ, π model has been very successful in the description of long range coupling constants although, again, it is a topic of critical discussion.¹⁸

The σ, π model of nJ begins with the recognition that the contact contribution depends on the probability that the electrons, involved in the transmission of nJ , are found at the sites of the coupled nuclei; the protons in ethylene, for example. However, electrons in π orbitals have a zero probability of being found at the nuclear sites—p orbitals have nodes in the plane of the nuclei.

This conundrum is resolved by the invocation of a σ, π spin polarization mechanism, rather similar to that involving the σ electrons in (7). The single p or π electron in (20) and (21) spin polarizes the σ electrons in the C–H bond and leads to an ‘up’ or a ‘down’ arrangement of the proton spin (crossed arrow). By Hund’s rule, (20) is energetically favored. This fact is represented by the σ, π hyperfine interaction parameter $Q_{\text{CH}}^{\text{H}} < 0$ (in the subscript the first symbol represents the atom carrying the unpaired spin, the two subscripts together indicate the bond being spin polarized, and the superscript designates the nucleus coupled to the unpaired electron). Q_{CH}^{H} is negative by definition—the p electron and the proton spins are parallel. Consolidation of this fact with the bonding in ethene (22) where the π electrons are spin correlated (paired off), leads to a π electron spin coupling pathway as shown, in addition to that through the σ bond. It is then found that $^3J^{\pi} \propto Q_{\text{CH}}^{\text{H}} \times Q_{\text{CH}}^{\text{H}}$, yielding about +1.5 Hz, which adds to $^3J^{\sigma}$ which is an order of magnitude larger, to give $^3J^{\pi} + ^3J^{\sigma}$.

Now, consider butadiene (23). The bond between the middle carbon atoms is not a single bond but has considerable ‘double-bond character’; it is said to have a mobile bond order between zero and one, a result of the relatively easy delocalization of π electrons (unlike σ electrons). The magnitude of $^5J^{\pi}$ depends on how strongly the p electrons at the central carbon atoms [dashed lines in (23)] are spin correlated. The

hyperfine interaction at each end of the coupling pathway provides the link between the σ and π electron systems. Note that $^5J^\pi > 0$, the proton spins in (23) being antiparallel, even though $Q_{\text{CH}}^{\text{H}} < 0$. The sign of J^π depends on the number of intervening bonds, being positive for n odd and negative for n even. Note also that this mechanism implies equal $^5J(\text{H,H})$ values in (23), i.e. the values are independent of the configuration at C-4. The observation that 5J_t is 1.3 Hz whereas 5J_c is 0.6 Hz implies a contribution to 5J_t from the σ electrons, $^5J^\sigma$. The coupling mechanisms discussed above for $^4J(\text{H,H})$ allow for two vicinal–vicinal interactions involving the central C–C bond in each and thus are expected to contribute most efficiently for an all-*trans* arrangement of the intervening bonds [extend structure (13)].

An estimate of $^5J^\pi$ can be made using the ‘methyl group replacement technique’, the use of which involves the following argument. In (24), a proton in one C–H bond of a methyl group has a positive hyperfine interaction $Q_{\text{CCH}}^{\text{H}}/0$ with the electron in the p orbital on the neighboring carbon atom [a so-called β -interaction, contrasting with the α -interaction in (20)]. Furthermore, $Q_{\text{CCH}}^{\text{H}} \propto \sin^2 \theta$ so that $Q_{\text{CCH}}^{\text{H}}$ is largest when the sigma C–H bond lies in the plane containing the p orbital (best overlap). For a rotating methyl group, with three C–H bonds, $\sin^2 \theta$ has an average value of 0.5.

It then turns out that $Q_{\text{CCH}}^{\text{H}} \approx -Q_{\text{CH}}^{\text{H}}$, with the consequence that $^6J^\pi(\text{H,CH}_3) \approx -^5J^\pi(\text{H,H})$. From the data on (23) it follows that $^5J^\pi \approx 0.7$ Hz and $^5J^\sigma \approx 0.6$ Hz. The model is not exact, of course, but has been used to estimate π electron contributions to nJ in a variety of molecules, including cumulenes ($\text{CH}_2=\text{C}_n=\text{CH}_2$) and acetylenes [$\text{HC}-(\text{C}\equiv\text{C})_n-\text{CH}$]. In such molecules, the extended spin correlation of the π electrons is relatively high,² leading to significant nJ for n as large as 9. Note that, as the mobile bond order of the central C–C bond in (23) decreases (dashed lines), $^5J^\pi$ will also decrease in magnitude. In this sense $^nJ^\pi$ is a measure of π electron delocalization: the mobile bond order in ethene (22) is unity, is about 0.4 for the central C–C bond in (23), and is less than unity for the other two C–C bonds. The use of $^nJ(\text{H,CH}_3)$ in testing the extent of delocalization in various molecules is described in a later section of this article.

5.2 Allylic and Homoallylic Couplings: $^4J(\text{H,H})$ and $^5J(\text{H,H})$

The $\sin^2 \theta$ dependence of $Q_{\text{CCH}}^{\text{H}}$ has many stereochemical applications, only two examples of which can be given here. $^4J_c(\text{H,CH}_3) \equiv ^4J_c$ and $^4J_t(\text{H,CH}_3) \equiv ^4J_t$ in propene (25) are called ‘allylic coupling constants’ and have values of -1.7 and -1.3 Hz, respectively. If the σ component of 4J were to vanish and the conformation of the methyl group was exactly the same as that in (25), but with rapid interconversion so that each C–H bond sampled each of the three values of θ (namely 0° , 120° , and 240°), then $\langle \sin^2 \theta \rangle$, the average value of $\sin^2 \theta$, would be 0.5. Actually, for free rotation of the methyl group, $\langle \sin^2 \theta \rangle$ is also 0.5, a consequence of the three-fold symmetry of a methyl group (a CH_2X group has lower symmetry, with important consequences for the derivation of internal rotational potentials, as described below). It would follow that 4J is a measure of the magnitude of $^3J^\pi$ in ethene ($Q_{\text{CH}}^{\text{H}} \approx -Q_{\text{CCH}}^{\text{H}}$).

However, because in (25) $^4J_c \neq ^4J_t$, the argument is only semiquantitative. The inequality may be attributable to the presence of $^4J^\sigma$. Thus, if the all-*trans* arrangement [see (13)] is most effective for $^4J^\sigma$, giving a positive contribution to 4J_t , a rough assessment of $^3J^\pi$ in ethene would be $+1.7$ Hz. The true situation is more complex;¹¹ nevertheless, large negative 4J values are expected and observed for $\theta \approx 90^\circ$. An example in which $^4J \propto \sin^2 \theta$ is (26), where the ratio of the two coupling constants is 1.5, as compared with a ratio of 1.4 for the corresponding values of $\sin^2 \theta$. To within the combined errors of the J values and the two angles, the relationship is very likely satisfied.

Homoallylic coupling constants $^5J(\text{H,H})$ arise from protons in C–H bonds flanking the double bond at both ends. Hence $^5J(\text{H,H}) \propto Q_{\text{CCH}}^{\text{H}} Q_{\text{CCH}}^{\text{H}} \propto \sin^2 \theta \sin^2 \theta'$, where the two torsional angles θ and θ' are analogous to those in (25).

A somewhat subtle stereochemical problem involves the degree of nonplanarity of 1,4-dihydrobenzene (27a)–(27c). If the equivalent (isoenergetic), nonplanar conformers (27a) and (27c) are the most stable ones, they may interconvert via the planar conformer (27b). The molecule is then said to undergo ‘conformational isomerization by inversion’. The potential energy function opposing inversion has two minima, as indicated; the speed of inversion depends on how the available thermal energy compares to the potential hindering the inversion. Alternatively, the most stable conformer may be (27b). Then the internal potential has a single minimum; nonplanar conformers occur with decreasing probabilities as the bending angle α deviates increasingly from 180° .

In (27b), the angles θ and θ' are 60° for an idealized geometry, but are not equal in (27a). Hence ${}^5J_c = J_t$ in (27b), but ${}^5J_c \neq {}^5J_t$ in (27a). In solution ${}^5J_c = 1.2 {}^5J_t$, from which it might be deduced¹⁹ that α is about 172° . The derivation of α assumes two rigid forms (27a) and (27c), a so-called 'two-site analysis' in which the measured values of 5J_c and 5J_t are simple averages of their values in these conformers. However, another interpretation holds that torsion about the C–C bonds of a stable, planar (27b), producing nonplanar conformers, would also cause the inequality ${}^5J_c > {}^5J_t$, so that either potential curve could correspond to observation. In fact, today the available evidence from various sources is that (27b) is the stable form.

6 AROMATIC MOLECULES

6.1 Some Coupling Mechanisms

In benzene (28) the indicated ${}^{3,4,5}J(\text{H,H})$ are of obvious use in assigning substitution sites in derivatives of (28). ${}^4J(\text{H,H})$, corresponding to an all-*trans* arrangement, has only a small π component. The ${}^6J(\text{H,CH}_3)$ value of -0.60 Hz in toluene (29) indicates that ${}^5J(\text{H,H})$ in (28) is mainly J^π , while the ${}^7J(\text{CH}_3, \text{CH}_3)$ value of -0.60 Hz in (30) implies $Q_{\text{CH}}^{\text{H}} = -Q_{\text{CCH}}^{\text{H}}$ in these compounds. Furthermore,²⁰ in (31), which represents derivatives of anisole ($\text{X} = \text{O}$), thioanisole ($\text{X} = \text{S}$), and ethylbenzene ($\text{X} = \text{CH}_2$), it is true that ${}^5J(\text{C,C}) = -1.50 {}^6J(\text{C,H}) + 0.02$ and ${}^6J(\text{C,C}) = -0.37 {}^5J(\text{C,C}) + 0.02$. The signs and relative magnitudes of the corresponding hyperfine interaction parameters near C-4, as in (32), are then $Q_{\text{CH}}^{\text{H}} = -Q_{\text{CCH}}^{\text{H}}$, $Q_{\text{CH}}^{\text{C}} = -1.50 Q_{\text{CH}}^{\text{H}}$, and $Q_{\text{CC}}^{\text{C}} = 0.56 Q_{\text{CH}}^{\text{H}}$. Such relationships also hold for other nuclei in the side chain, such as ${}^{19}\text{F}$, typified by (33), showing that the π -electron mechanism is dominant for the indicated ${}^{5,6,7}J$ couplings and that they depend on $\sin^2\theta$.

6.2 Internal Rotational Potentials from Long-Range Coupling Constants

When conformations are well defined, that is when the barrier to interconversion between conformers is large

compared to the thermal energies (see Section 1), the angle dependence of a long-range coupling constant is a good indicator of conformation. An example from aromatic chemistry is a benzaldehyde derivative (34). ${}^5J(\text{H,CHO})$ is apparently a ${}^5J^\sigma$ and, as such, is large for the all-*trans* pathway. If the indicated J values are correct, then measurement of ${}^5J(\text{H,CHO})$ yields the populations of (34a) and (34b) by simple proportion. This simple strategy works well because nonplanar conformers are negligible at ambient temperatures.

Suppose, however, that the barrier to rotation about the ring–CHO bond were very small compared with thermal energies. In such circumstances the idea of one or a few conformations would lose utility because many angles θ would be of similar probability. In the limit of a zero barrier, an infinite number of conformations (all values of θ) would be present.

When the barrier to internal rotation about a bond is small, it is advantageous to discuss stereochemical problems in terms of the internal rotational potential $V(\theta)$, which gives the relative energy of the molecule at each value of θ . Can long range coupling constants be used to determine $V(\theta)$? In some instances, certainly. These statements are best illustrated with one of the many examples available.

Consider benzyl fluoride (35) and the potential hindering rotation about the exocyclic C–C bond. If (35b) and (35c) represent extrema in the potential, the barrier $V(\psi)$ [or $V(\theta)$] is said to be two-fold because it repeats itself twice between 0° and 360° [see (36)]. The barrier turns out to be solvent dependent,²¹ which is an advantage in the following logic. One has ${}^6J(\text{F,H}) = {}^6J_{90}^{\text{F}}(\sin^2\psi)$ and ${}^6J(\text{H,H}) = {}^6J_{90}^{\text{H}}(\sin^2\theta)$; here ${}^6J_{90}$ is the value when C–F or C–H lies 90° out of the benzene ring plane, and the angle brackets indicate an average over the internal motion controlled by the potential. The roughly tetrahedral geometry at the carbon atom of the CH_2F group implies $\langle \sin^2\theta \rangle = 0.75 - 0.5\langle \sin^2\psi \rangle$. It follows that measurements of the two coupling constants in two different solvents yield both the ${}^6J_{90}$ values as well as $\langle \sin^2\psi \rangle$ and $\langle \sin^2\theta \rangle$ in each solvent. The latter can be calculated²² by quantum mechanical or classical methods as a function of the internal potential, V_2 . A comparison between the theoretical $\langle \sin^2\psi \rangle$, say, and its experimental values yields V_2 in the two solvents. Together with measurements of ${}^5J(\text{F,C})$, also a J^π , one finds that V_2 is 3.2 kJ mol^{-1} in very polar solvents and 0.7 kJ mol^{-1} in nonpolar solvents. Curve (a) in Figure 2 describes the potential form. Extrapolation to the vapor phase implies that the potential is now as in curve

Figure 2 Twofold internal rotational potential, as applicable to (35b)

(b) in Figure 2, which is qualitatively confirmed by high-level molecular orbital computations on the free molecule. The change in phase of the potential is of interest in the theory of solutions. A phase change can also be induced by substituents on the ring. Each derivative will possess its own, distinctive, solvent dependent, internal rotational potential, the determinations of which present as yet unmet challenges for the various spectroscopic and theoretical methods (*Liquid Crystalline Samples: Structure of Nonrigid Molecules*).

6.3 Stereospecific Long Range Coupling Constants in Extended Aromatic Molecules

Examples of nJ with n as large as 11 are provided by ${}^nJ(\text{F},\text{F})$ and ${}^nJ(\text{F},\text{C})$ in (36) and (37). It is known that the torsion angle θ in (37) is effectively 90° , the two benzene planes being perpendicular, and that it is near 45° in (36). Note that ${}^{7,8}J(\text{F},\text{C})$ and ${}^9J(\text{F},\text{F})$ vanish when $\theta \approx 90^\circ$, indicating that π electron spin correlation has been broken across the central C-4–C-5 bond; there is no π electron conjugation or delocalization between the two aromatic moieties in (37). The finite values of these nJ can be related²³ to $\cos^2\theta$ in (36), as can ${}^{11}J(\text{F},\text{F})$ when the fluorine atoms in (36) are replaced²⁴ by CH_2F groups. Of course, ${}^{11}J(\text{F},\text{F})$ will, in addition, be proportional to $\sin^2\psi$, where ψ is the angle by which the C–F bond turns out of the benzene plane, as in (35b); thus ${}^{11}J(\text{F},\text{F}) \propto \sin^2\psi \cos^2\theta$.

A composite mechanism must also operate for ${}^6J(\text{F},\text{C})$ at site 6 in (36) and (37) because it is larger in (37). The C-5–C-6 bond undergoes a hyperfine interaction with the π electron at C-4, characterized by Q_{CC}^{C} and analogous to Q_{CH}^{H} in (32), which is maximal in (37) and hence varies as $\sin^2\theta$. The other part of the mechanism varies as $\cos^2\theta$, just as for ${}^{7,8}J(\text{F},\text{C})$; hence ${}^6J(\text{F},\text{C}) = A\sin^2\theta + B\cos^2\theta$. Such composite mechanisms also occur in other conjugated systems,

an excellent example being styrene,²⁵ where an alkenic group is bonded to an aromatic system.

6.4 Electron Delocalization and Long Range Coupling Constants

Aromaticity is related to the delocalization of π electrons, leading to mobile bond orders. The structure and reactivity of a molecule are sensitive to the extent of delocalization. There are various definitions of mobile bond order, but all agree that the bond order is zero for a C–C bond, unity in ethene (19) or propene (25) and 2 for a triple bond, as in (4). Clearly, the allylic ${}^4J(\text{H},\text{CH}_3)$ in (25) depends on the π electrons. If delocalization were to decrease the mobile bond order, then the magnitude of ${}^4J(\text{H},\text{CH}_3)$ would also decrease. This idea has been exploited, particularly by Sternhell and co-workers,²⁶ to determine the mobile bond orders in aromatic systems; however, in this case 4J is called a ‘benzylic J ’. In (38)–(45), the degree of delocalization is evident from the indicated 4J . If -0.70 Hz in (41) is a measure of the delocalization of the π electrons in the prototypical aromatic molecule, benzene, then in (42), for example, some localization (double bond fixation) has been induced by the strong conjugation between the hydroxyl and nitro groups. In the cyclophane (45) the benzene moiety is strongly nonplanar, yet delocalization of the π electrons is still substantial.

Of course, ${}^7J(\text{CH}_3,\text{CH}_3) \equiv {}^7J = 0.60\text{ Hz}$ in 1,4-dimethylbenzene (30) is also a measure of delocalization of π electrons. The pyridine derivatives (46)–(48) are delocalized, whereas the benzoquinone (49) and the borazine (50) are not. Borazine itself is isoelectronic and isostructural with benzene and is sometimes considered as an inorganic analog of benzene.

6.5 $^4J(\text{C},\text{C})$ in Some Condensed Aromatics

$^4J(\text{C},\text{C})$ in condensed aromatics such as (51)–(54) are thought²⁷ to be transmitted mainly via the π electrons, which are delocalized to a large extent. $^4J(\text{C},\text{C})$ was measured by enriching with ^{13}C at the position marked by an asterisk; the sign of $^4J(\text{C},\text{C})$ is known only in the case where it is given in the structures. The generalized mobile bond order between the coupled sites vanishes for these even alternant hydrocarbons,²⁸ which suggests very little spin correlation of the electrons at these sites. Furthermore, the atom–atom polarizabilities, which might in this connection be thought of as indicating how the π electron at the second site responds to a perturbation at the first site, are also very small for the indicated atoms. However, the atom–atom polarizability involving the penultimate site in the shortest coupling path, indicated by solid triangles in (51) and (52), is relatively large except for the 4J of 0.3 Hz in (53) and that of 0.0 Hz in (54). This observation may represent an accidental coincidence; it has not been discussed in the scientific literature, but may be worth further study. It may be noted that $Q_{\text{C}\text{C}}^{\text{C}}$ is sizeable and negative, and contributes to a negative $^4J(\text{C},\text{C})$ because it measures the hyperfine interaction of a π electron at the nearest carbon atom (solid spade) with the ^{13}C nucleus at the coupled site (solid circle). In this connection it would be useful to have many more $^nJ(\text{C},\text{C})$ values. There now exist methods²⁹ for finding nJ for unenriched molecules.

6.6 A Unique Conformation Determined from $^nJ(\text{H},\text{H})$

Were a chemist asked to predict the conformation of 2-hydroxythiophenol (55) in solution, he or she might

well suggest an equilibrium among three planar structures, $\text{HS}\cdots\text{OH}$, $\text{HS}\cdots\text{HO}$, and $\text{SH}\cdots\text{OH}$. This suggestion depends on the knowledge that conjugation of the lone pairs of electrons on oxygen or sulfur with the aromatic π electrons creates a mobile bond order, $\text{C}\cdots\text{S}$ and $\text{C}\cdots\text{O}$ (partial double bonds), leading to planar structures with concomitant barriers to rotation about the exocyclic bonds. A more sophisticated chemist might also suggest that the $\text{HS}\cdots\text{HO}$ structure would be most stable because the electrically polar O^--H^+ bond would seek the lone pair on sulfur, forming an intramolecular hydrogen bond, thereby stabilizing this structure. Indeed, the vibrational spectrum of (55) in CCl_4 solution has been interpreted in terms of an equilibrium among three planar forms.

On analysis,³⁰ the ^1H NMR spectrum of such a solution yields nine $^nJ(\text{H},\text{H})$ ($4 \leq n \leq 6$) for protons in the side chains. These demonstrate unequivocally that the perpendicular conformation depicted in (55) is dominant. In view of the previous discussions, the large magnitudes of $^nJ(\text{SH},\text{H})$ and the stereospecific $^5J(\text{OH},\text{H}-4)$ are consistent only with the indicated conformation, the one in which the $\text{S}-\text{H}$ bond lies in a plane roughly perpendicular to that of the rest of the molecule. The polar $\text{O}-\text{H}$ bond twists the 3p lone pair into the molecular plane, forming a hydrogen bond, and the $\text{S}-\text{H}$ bond must therefore twist out of that plane. The formal $^5J(\text{OH},\text{SH})$ is an example of one kind of proximate J , in this case most probably being transmitted via the hydrogen bond.

7 PROXIMATE LONG RANGE COUPLING CONSTANTS

The stereochemistry of a molecule may be such that two of its fragments, while separated by many formal bonds, may still be proximate. Couplings between nuclei in the different fragments^{6,31} are called 'proximate' (originally, 'through space'). An example is the $^5J(\text{F},\text{F})$ of 174 Hz in (56),³² which is thought to be transmitted by the interaction of the lone pair electrons on the two fluorine atoms. The internuclear distance is well within the sum of the van der Waals radii of the atoms. Another example is (57) where the proximity mechanism is relayed via an $\text{H}-\text{F}$ overlap to yield a $^4J(\text{F},\text{C})$ the magnitude of which decays exponentially with the $\text{H}-\text{F}$ distance.³³ The scientific literature abounds with examples of proximate coupling constants between many different pairs of nuclei. Their stereochemical use is obvious. (See also *Coupling Through Space in Organic Chemistry*)

The most striking example³⁴ is a J of about 17 Hz between fluorine nuclei of 5-fluorotryptophan residues placed in the enzyme dihydrofolate reductase. The fluorine atoms are separated by dozens (n) of covalent bonds, yet must approach each other to within about 0.3 nm, a consequence of the folding pattern of the protein. The value of n may well be a record.

8 THE FUTURE OF LONG RANGE COUPLING CONSTANTS

One of the goals of mathematical chemistry is the computation of accurate stereochemical properties of molecules. Great progress has been made towards this goal, particularly for molecules for which the accurate measurement of small nJ values is feasible. As computers become faster, the general computation of nJ for reliable theoretical stereochemistries may also become a reliable procedure. Until then, measurements of nJ will likely retain their empirical utility. Furthermore, nJ values are normally measured in solution, in which perturbations by solvent molecules of conformational equilibria can be large; the nJ values may serve as checks of the theoretical descriptions or models of such perturbations.

1 INTRODUCTION

The subject of supramolecular chemistry is the design, preparation and study of discrete chemical systems composed of several units linked by non-covalent bonds to form a well-defined structure under thermodynamic control.^{1–4} This definition is sometimes applied loosely to include species formed by several molecular entities that are not in equilibrium with the separate components or are non-discrete. The first situation applies to complexes that have very large energy barriers to dissociation. The second includes polymeric materials or solid-state systems in which one of the components forms a crystalline lattice that can accommodate the other component.

NMR has been the most important analytical tool for the study of supramolecular systems in solution and it has also been applied extensively, along with X-ray and other techniques, to solid systems. The success of NMR in this field is due to its ability to (i) study complex chemical systems in equilibrium, (ii) report about their symmetry properties, (iii) determine the conformation of the individual components and their mutual interactions and (iv) characterize the dynamic behavior of the system in a wide range of time scales. The role of NMR in supramolecular chemistry has been recently reviewed.^{5,6}

In this review we shall give an overview of the structural and dynamic problems encountered in supramolecular chemistry and of the methods that are used to address them.

2 DETECTION OF SUPRAMOLECULAR INTERACTIONS BY NMR METHODS

2.1 Supramolecular Complexes Involving Several Components

Intermolecular interactions can affect all the NMR observables. Perturbations in the environment of the different nuclei are reflected in chemical shift changes. Differences in the size and shape of the complex, compared to the isolated molecules, result in differences in diffusion and relaxation experiments.

Because of their easy availability, changes in chemical shifts are extensively used to detect the formation of supramolecular complexes. The association constants and the stoichiometry of the process can be extracted by fitting titration curves to the equations that describe the binding.

Binding is a chemical exchange process and its effect on the observed NMR spectra depends on the lifetime of the complex. When it is long, compared to the reciprocal of the frequency difference with respect to the uncomplexed form, the complex contributes a new set of signals and the equilibrium concentrations of the complex and free forms can be determined by integration. When exchange is fast, average signals are observed at chemical shifts that are the weighted average of those of all the species that participate in the equilibrium. Intermediate exchange rates affect the line shape in a well-determined way and kinetic information can be extracted.

Rate constants are temperature sensitive and experimental conditions, for which the process of interest is either in the fast or slow exchange regime, can usually be found.

The book by Connors discusses NMR methods for determining binding constants.⁷

For a 1 : 1 (*A*–*B*) complex the binding isotherm is given by

$$\delta_{\text{obs}} - \delta_{\text{free}} = \delta_{\text{complex}} - \delta_{\text{free}} \frac{K[B]}{(1 + K[B])} \quad (1)$$

where δ_{obs} is the observed chemical shift of a nucleus in species *A*. δ_{free} and δ_{complex} are the chemical shifts of *A* in the free state and in the complex. *K* is the association constant with ligand *B* and [*B*] is the concentration of free ligand. [*B*] can be replaced by the total concentration of *B* if $K[A] \ll 1$, where [*A*] is the concentration of free *A*. This condition is fulfilled when *B* is in large excess with respect to *A* or when binding is weak (*K* small).

The concentration range explored during a titration has to cover a substantial fraction of the binding curve in order to determine the binding constant meaningfully. It has been suggested that experimental conditions covering 20% to 80% of the maximum possible concentration of the complex have to be examined. This is achieved when the concentration of the observed component (*A*) is maintained at about one tenth of the dissociation constant (K^{-1}) and the added ligand *B* is varied from this concentration to about ten times the dissociation constant.⁸

When binding is strong, the dissociation constant is very small and the optimal concentration of the observed species would be very low, causing sensitivity problems. In this case a dilution protocol may be used. In this type of experiment, an equimolar solution of *A* and *B* is prepared and spectra are observed after successive dilution steps. Obviously, dilution is the only available possibility to study self-association, i.e., when *A* = *B*.

The stoichiometry of the complex can be determined using Job's method of continuous variation. In this method the ratio of the two species *A* and *B* is varied, while keeping the total concentration, [*A*]₀ + [*B*]₀, constant. The concentration of the complex will be maximal when [*A*]₀ = [*B*]₀ for an *AB* complex but when [*A*]₀ = 2[*B*]₀ for an *A*₂*B* complex.

The observed chemical shift δ_{obs} is related to the concentration of the complex and the total concentration of *A*, [*A*]₀, by

$$\frac{(\delta_{\text{obs}} - \delta_{\text{free}})}{(\delta_{\text{complex}} - \delta_{\text{free}})} = \frac{[\text{complex}]}{[A]_0} \quad (2)$$

If the sum of the concentrations of *A* and *B* are constant, $[A]_0$ is proportional to X_A and a plot of $(\delta_{\text{obs}} - \delta_{\text{free}})X_A$ versus X_A has a maximum at a value of $X_A = n/(n + 1)$ for a complex A_nB .

Other NMR parameters that have different values for a molecule free in solution or when forming part of a complex can be used to derive binding constants.

In the fast exchange limit, the observed relaxation rate constant *R* is a weighted average of the relaxation rate constants of the free molecule (R_{free}) and the complex (R_{complex}). In complete analogy with the chemical shift situation, the binding isotherm for 1 : 1 binding is given by

$$R_{\text{obs}} - R_{\text{free}} = R_{\text{complex}} - R_{\text{free}} \frac{(K[B])}{(1 + K[B])} \quad (3)$$

Changes of the relaxation rates in complexes are associated to changes in correlation time, related to the size and shape of the molecule, or to changes in relaxation mechanisms. However, application of equation (3) is independent of the mechanistic details.

Diffusion coefficients can also be used to obtain binding constants. Diffusion coefficients depend on the size and shape of the molecule. When the two interacting species are very different in size, the diffusion coefficient of the complex can usually be assumed to be equal to that of the larger molecule.

Correlation times and diffusion are very sensitive to the viscosity of the solution, and relaxation time and diffusion coefficient measurements have to be corrected for changes in viscosity of the solution during the titration.

2.2 High Symmetry Supramolecular Complexes between Identical Molecules

When complexes between identical molecules are formed with large association constants, the NMR spectra of the isolated component may not be available under the experimental conditions (solvent, temperature) that promote complex formation. Detecting and characterizing the formation of supramolecular complexes by NMR is then a non-trivial task.

Supramolecular complexes between identical molecules are earmarked by their symmetry and this is faithfully reflected in their NMR spectra.⁹ Most of the examples that can be found in

Figure 1 (a) Chemical structure of the precursor of the 'tennis ball'. When $R_1 \neq R_4$ and $R_2 \neq R_3$ the monomer has a plane of symmetry but the dimeric capsule is chiral and the two NH groups in each glycoluril are not equivalent. (b) Dissociation and reassociation of the dimer leads to racemization. (Reproduced with permission from Ref.⁶ from Elsevier Science © 2001)

the very extensive literature about characterization of specific supramolecular species can be classified according to Box 1.

A few examples will clarify the scenarios presented in Box 1. These examples will also serve to introduce some of the most extensively studied supramolecular families. The 'tennis ball' capsule illustrates the situation 1(a) of Box 1. The 'tennis ball' is a high symmetry dimer held together by intermolecular hydrogen bonds that define an interface with a shape reminiscent of the seam in a tennis ball.¹⁰ The monomer is a curved molecule based on two glycoluril groups and a durene spacer (Figure 1). The assembly has D_{2d} symmetry and the NMR spectra obtained in benzene- d_6 or $CDCl_3$ reflects the two symmetry planes expected for the isolated molecule. Early evidence for the formation of this capsule was derived from the chemical shifts of the NH protons, suggesting hydrogen bonding, and the observation of strongly shielded signals from small hosts, like methane or xenon, that were included in the capsule.

The introduction of two differently substituted glycoluril groups on the durene spacer reduces the symmetry of the monomer to C_s . However, the dimer, a chiral (C_2) capsule, has no symmetry planes and the two NH groups in each glycoluril unit are not equivalent. This is the situation indicated in point 2(a) of Box 1.

Box 1 Detection of complex formation between identical molecules by comparing the observed NMR spectrum with that expected from the isolated component

- The number of NMR signals reflects an apparent symmetry equal to that of the isolated component.
 - In a rigid system, this implies that the components are symmetry related. Chemical shift arguments are the only evidence for complex formation.
 - The symmetry of the complex results from fast average of lower symmetry arrangements. NMR spectra at low temperature may show signal splitting.
- The number of signals in the NMR spectrum of the complex increases, reflecting a lower local symmetry.
 - The relative disposition of the components destroys symmetry elements present in the isolated components.
 - A fast local internal motion, which resulted in average signals in the isolated component, is slowed down as a result of complex formation.
 - The interacting molecules become fixed in a low symmetry conformation in the complex.
- Multiple sets of signals are observed.
 - The subunits, although constitutionally identical, are not related by symmetry in the complex. The integration of the NMR signals reflects the complex stoichiometry.
 - Isomeric complexes, possibly of different symmetry, are formed. Integration reflects the relative populations.

Figure 2 Resorcin[4]arene building blocks. (a) Parent resorcin[4]arenes have free OH groups that can participate in intra- and intermolecular hydrogen bonds. (b) Bridged resorcin[4]arene are known as cavitands. (c) Carcerands are covalent dimers of cavitands. A carcerand with an irreversibly trapped guest is called a carceplex. (Reproduced with permission from Ref.⁶ from Elsevier Science © 2001)

Bowl-shaped cyclic molecules can define a cavity by face-to-face dimerization. This is the case of cavitands, that contain a resorcin[4]arene skeleton (Figure 2).¹¹ Cavitand-based non-covalent dimer capsules, stabilized by intermolecular hydrogen bonds, and covalent dimers, with linkers between the two moieties, share a number of structural characteristics, including their ability to incorporate structures in the internal cavity. Molecules incorporated in the covalent dimer during their preparation are permanently trapped. Appropriately, the covalent dimers are called carcerands and their complexes with small molecules are called carceplexes. The X-ray structures of different carceplexes or non-covalent capsules show interbowl twists of 13–21°. The solution NMR spectra suggest that resorcinarene capsules and carcerands are highly symmetric achiral structures, compatible with a D_{4h} symmetry. This is the result of fast interconversion between dimers differing in the sign of the relative twist between the two halves of the dimer. These two forms have been called twistomers. At low temperature, interconversion between twistomers is slow and the dimer loses all symmetry planes. The D_{4h} symmetry is then reduced to D_4 (Figure 3). This symmetry reduction is not reflected in the NMR spectra under achiral conditions but leads to signal duplication when the carceplex contains a chiral

guest. The observation of signal splitting at low temperature was listed as situation 1(b) in Box 1.

A different family of bowl-shaped molecules, the calix[4]arenes,¹² can be modified to form capsules by introducing urea substituents in one of the rims (Figure 4).^{13,14} Urea groups from two different molecules are interdigitated and form a cyclic array of hydrogen bonds. Under conditions in which capsules are not formed, e.g., in the presence of solvents that can compete for the formation of hydrogen bonds, fast rotation about the C–N bond linking the urea group to the calixarene results in a symmetrical species in which the macrocyclic aromatic protons are all equivalent. In the dimer, reorientation of the urea group is not possible, as it requires breaking the cyclic hydrogen bond array.

As a consequence, formation of the capsule can be determined by NMR from the observation of the splitting of the signal of the aromatic protons of the calixarene into two *meta* coupled doublets, an example of the situation indicated in point 2(b) of Box 1. When the symmetry of the precursor calix[4]arene is lowered from C_{4v} to C_{2v} by placing two different substituents in alternate positions, the symmetry of the dimer is reduced to C_2 . This is a consequence of the directionality of the hydrogen bond array and the interdigitation of the urea groups (cf. Figure 7 below). In this dimer, the two calixarenes are non-equivalent and duplicated signals are observed, as prescribed in point 3(a) of Box 1.

Helicates are discrete supramolecular complexes formed by one or more covalent organic strands wrapped about and coordinated to a series of ions.¹⁵ The ions define a helical axis. The otherwise flexible organic strand becomes fixed in a helical structure that is intrinsically chiral (Figure 5). This situation, listed as point 2(c) in Box 1, is reflected in the NMR spectra of methylene groups that are rendered diastereotopic.¹⁶ This allows double stranded helicates to be easily distinguished from isomeric non-helical side-by-side complexes, a possibility contemplated as point 3(b) of Box 1.

The same line of thought can be applied to the analysis of higher order supramolecular complexes involving different types of molecules. For example, the melamine-cyanuric acid rosettes studied by Whitesides and coworkers are discrete aggregates composed of four molecules: one

Figure 3 Due to the relative twisting of the two moieties, the minimum energy conformations of cavitands have no symmetry plane, even $R = R'$. At low temperature interconversion of the two enantiomers (called 'twistomers') is slow. Under these conditions, enantiotopic groups in the included guest may become diastereotopic. (Reproduced by permission of the American Chemical Society © 1999)

Figure 4 (a) A urea substituted calix[4]arene. (b) Schematic representation of the dimerization of tetra urea calix[4]arenes, interdigitated urea groups form the array of hydrogen bonds. Exchange between *A* and *a* or *B* and *b* reflects the rotation of the urea group that is slowed down dramatically when the capsule is formed. In the cone conformation adopted by the calix[4]arene in the capsule, protons from neighbor aromatic rings (e.g., *a* and *B* or *b* and *A*) show strong NOEs. When $R' = R''$, $A \equiv B$, $a \equiv b$ and the NOESY (e.g., *a*-*B*) and exchange (e.g., *a*-*A*) cross-peaks overlap. (Reproduced with permission from Ref.⁶ from Elsevier Science © 2001)

Figure 5 (a) Chemical structure of an organic ligand that can form helicates with Cu^+ . (b) Schematic representation of two double stranded complexes $[\text{Cu}_2\text{L}_2]^{2+}$. When $Y = N$ a helicate with D_2 symmetry is formed and the methylene groups in the ligand give *AB* type spectra. When $Y = CH$ a side-by-side complex with C_{2h} symmetry is formed and the methylene groups appear as A_2 singlets. (Reproduced with permission from Ref.⁶ from Elsevier Science © 2001)

tris-melamine, $\text{Hub}(\text{M})_3$, and three isocyanuric acid, CA, molecules (Figure 6).¹⁷ Aggregates of two different symmetries, C_3 and C_1 , are substantially populated and the imide proton region of the ^1H -NMR spectra of some of the rosettes show eight signals, two from the C_3 isomer and six from the C_1 isomer. This is an example of the situation 3(b) of Box 1 applied to systems with two components.

2.3 Supramolecular Complexes between a Large and a Small Molecule

Formation of supramolecular complexes between molecules of different sizes causes substantial changes in the hydrodynamic properties of the smaller component that can be detected

by NMR methods. Both translational and rotational diffusion coefficients are affected.

Translational diffusion coefficients are determined by NMR using pulsed field gradient spin-echo (PFGSE) experiments.¹⁸ After initial excitation, magnetization from molecules in different positions within the sample acquires different phases by the application of a pulsed field gradient. As a result, the net magnetization from the complete sample becomes zero. If the position of the molecules does not change, application of a second gradient pulse causes refocusing of the magnetization. However, diffusion of the molecule during the interval between the two gradient pulses results in an attenuated signal.

Quantitative determination of the translational diffusion coefficient can be achieved by fitting the signal intensity of a

Figure 6 (a) Tris-melamine $\text{Hub}(\text{M})_3$ and its schematic representation, where X is a rigid spacer. (b) Schematic representation of a $\text{Hub}(\text{M})_3:\text{CA}_3$ aggregate. (c) Chemical structure and schematic representation of a melamine-cianuric acid (CA) hydrogen bond array to form a rosette. (d) The four possible isomers for the complex $\text{Hub}(\text{M})_3:\text{CA}_3$. The two enantiomers shown on top present C_3 symmetry, the enantiomers on bottom do not have elements of symmetry (C_1). (Reproduced by permission of the American Chemical Society © 1993)

series of PFGSE experiments with different gradient strengths to the Stejskal–Tanner¹⁹ equation:

$$I(\Delta, \delta, G) = I_0 \exp\left(-\gamma^2 G^2 \delta^2 \left(\Delta - \left(\frac{\delta}{3}\right)\right)\right) D \quad (4)$$

where D is the translational diffusion coefficient, Δ corresponds to the delay between gradients, δ is the gradient duration, G is the gradient strength and γ is the gyromagnetic ratio.

Translational diffusion coefficients are related to the size and shape of the molecule. For a spherical object the diffusion coefficient can be calculated from

$$D = \frac{k_B T}{6\pi\eta r} \quad (5)$$

where, η is the solvent viscosity and r is the radius of the sphere. Similar analytical equations exist for ellipsoids and cylinders.²⁰ Methods to calculate translational and rotational diffusion coefficients for rigid molecules of arbitrary shape have been described.^{21,22}

Affinity NMR makes use of the large differences between the translational diffusion coefficients of small ligands and macromolecules. In this experiment, small, uncomplexed molecules are attenuated beyond detection by a PFGSE sequence. However, molecules that interact with the slowly diffusing large component are still observable and therefore can be identified, usually from a mixture of candidate ligands.

Association of small molecules can also be characterized sometimes by diffusion based experiments specially when the association involves a large number of components and leads to large polyhedral assemblies.²³

Rotational diffusion coefficients determine the relaxation rates. Transverse relaxation is fast in macromolecules resulting in broad lines that may even prevent the observation of the macromolecule or the complex. Cross-relaxation rates in the macromolecule and in the complex are also much faster than in the free small component. The intramolecular NOE (nuclear Overhauser effect) generated in the complex can be measured in the free molecule if the off-rate is large enough. Thus, the formation of the complex can be detected by the observation of intramolecular negative NOE values, typical of large molecules, in small molecules studied in the presence of a macromolecule with which they can interact. This effect is the well-known transferred NOE.^{24,25} Transferred NOE experiments provide information about the conformation of flexible ligands in the complex.

Interpretation of transferred NOE requires caution, because of fast spin diffusion involving spins in both the ligand and the macromolecule.

Intermolecular cross-relaxation is used constructively to detect ligand binding to macromolecules by the methods of NOE pumping and saturation transfer difference (STD).^{26,27} In NOE pumping experiments, a diffusion filter eliminates signals from all small molecules and those from the bound ligands are recovered by intermolecular NOE from the macromolecule. In the STD experiment, protons in the complex, including those from any bound ligand, are saturated by strong radiofrequency irradiation at a frequency where only signals from the macromolecule are absorbing, even if they are too broad to be observed. Fast spin diffusion transfers the saturation to the complete ensemble of protons in the complex.

Saturation is maintained after dissociation of the complex and results in a smaller intensity in the signals from molecules that can bind to the macromolecule. Thus ligands can be detected in a difference experiment.

3 DYNAMIC OF SUPRAMOLECULAR COMPLEXES

3.1 Interference between Exchange and Cross-Relaxation

Dynamic processes are an inherent part of the chemistry of supramolecular complexes. The definition of supramolecular complexes includes the fact that these entities are in equilibrium with their separated components implying that the processes of formation and dissociation have to be fast. In addition, other dynamic processes involving changes in the relative arrangement of the subunits in the complex can also take place. NMR methods are especially useful to study dynamic processes in equilibrium if they involve a change in the environment of NMR-active nuclei. This includes many degenerate processes that involve the interconversion between symmetry related forms of the same complex.

A typical situation involves the formation of a (racemic) chiral complex from achiral components. Enantiotopic groups in the isolated molecules become diastereotopic in the complex, and therefore NMR-distinguishable if the dissociation–reassociation process is slow with respect to the reciprocal of the chemical shift difference. Dissociation and random reassociation yields the starting isomer and its enantiomer with 50% probability and, when the rate is large enough, leads to coalescence of the signals from enantiotopic groups. The racemization rate is half the dissociation rate. The dissociation kinetics of the asymmetric tennis ball was determined by this method.²⁸

Racemization of chiral supramolecular complexes is not always associated to dissociation processes. This is the case, for example, of some helicates that can change the configuration around the different metal centers without dissociation. An experimental proof of intramolecular inversion of chirality is obtained by observing the coalescence of diastereotopic groups in the complex in the presence of excess ligand and showing that the signals from the free ligand are not affected.

Dynamic processes that are slow in the chemical shift time scale but faster than the relevant relaxation rates can be studied by 1D or 2D magnetization exchange techniques.

Chemical exchange and cross-relaxation have very similar effects on NMR spectroscopy. In fact, the same pulse sequence is used in EXSY (exchange spectroscopy) or NOESY (NOE spectroscopy) and the two experiments differ on whether the conditions chosen avoid cross-relaxation and emphasize chemical exchange or if cross-relaxation is the dominant effect.

Supramolecular complexes contain extensive intermolecular contacts and have long correlation times that makes cross-relaxation very efficient. In addition, composite cross-relaxation exchange pathways can transfer magnetization between distant sites. As a consequence, spin diffusion effects complicate the interpretation of NOESY/EXSY experiments in supramolecular complexes.

When cross-relaxation and exchange contribute to different cross-peaks, the process that is mainly responsible for the appearance of each cross-peak in NOESY spectra can be determined using ROESY (rotating frame Overhauser enhancement

spectroscopy) spectra, in which cross-relaxation and exchange peaks have opposite signs. Off-resonance effects and TOCSY (total correlation spectroscopy) coherence transfer complicate quantification of ROESY spectra.

Off-resonance ROESY uses an off-resonance spin-locking field forming an angle θ with the transverse plane. For small values of θ , off-resonance ROESY is similar to ROESY and for angles close to 90° , it gives results similar to those of NOESY spectra. For intermediate values of θ , the cross-relaxation contribution can be made to vanish, resulting in a pure exchange spectrum.

Figure 7 shows expansions of NOESY, ROESY and off-resonance ROESY spectra of a dimer of a urea-substituted, low-symmetry calix[4]arene in d_6 -benzene.²⁹ Notice that the two calixarene units are non-equivalent. The sense of rotation of the hydrogen bond array is what defines the 'top' and 'bottom' units. When the direction of the hydrogen bonds is reversed, the top and bottom units are exchanged. Separation of cross-relaxation and exchange is facilitated by the use of different substituents in adjacent aromatic rings.

Separate quantification of exchange and cross-relaxation rates from NOESY spectra is best carried out by a

Figure 7 (a) Schematic representation of the homomerization pathways for a low symmetry calix[4]arene. (b) Observed exchange cross-peaks in the EXSY experiment are indicated by arrows in a schematic formula of the dimer. (c–e) Partial 2D NMR spectra of the low symmetry calix[4]arene in d_6 -benzene (500 MHz, 298 K, $\tau_m = 300$ ms): (c) NOESY, (d) ROESY, (e) off-resonance ROESY ($\theta = 35.6^\circ$). Negative cross-peaks in (d) arising from cross-relaxation are plotted with a reduced number of contours. (Reproduced by permission of the American Chemical Society © 1997)

relaxation-plus-exchange matrix approach.³⁰ The intensity matrix (**I**) is related to the kinetic plus relaxation matrix (**L**), the relative population of the sites (**P**) and the mixing time τ_m by

$$I = \exp(\mathbf{L} \cdot \tau_m) \cdot \mathbf{P} \quad (6)$$

Matrix **L** can be obtained directly from the normalized experimental intensity **A** by taking the logarithm of **A** and dividing by the mixing time. This involves diagonalization of **A** as indicated in the following equations:

$$\mathbf{A} = \mathbf{I} \cdot \mathbf{P}^{-1} \quad (7)$$

$$\mathbf{A} = \mathbf{X} \cdot \mathbf{A} \cdot \mathbf{X}^{-1} \quad (8)$$

$$\mathbf{L} = \ln \frac{\mathbf{A}}{\tau_m} = \frac{\mathbf{X} \cdot (\ln \Lambda)}{\tau_m \cdot \mathbf{X}^{-1}} \quad (9)$$

This procedure has the advantage that spin diffusion is corrected for, allowing the use of longer mixing times. In particular, interference from composite exchange cross-relaxation pathways is minimized.

A more complicated situation arises when separate exchange and cross-relaxation processes involve the same pair of nuclei (cf. Figure 4, $R' = R''$). Direct analysis of the 2D spectra can only provide a composite rate constant. In order to separate the contributions, the different temperature dependencies of cross-relaxation and exchange processes can be used. As an alternative, EXSY spectra measured at different magnetic fields but at the same temperature will have different contributions from cross-relaxation but the same exchange effects. Finally, in some instances in which the geometry of the system is fixed and well known (e.g., pairs of methylene protons) the cross-relaxation rate can be calculated from independent measurements of the correlation time of the complex.

3.2 Dynamics of Hosts: Catenanes and Rotaxanes

The especially rich dynamic behavior found in catenanes and rotaxanes has been studied extensively by NMR.^{31,32}

Strictly speaking, catenanes and rotaxanes are not supramolecular complexes but true molecules formed by several interlocked components. Catenanes have different topology to the separate components and are said to possess 'topological bonds'. Rotaxanes are held together by steric or other kinds of hindrance to dethreading of a cyclic component from a linear one.

Both catenanes and rotaxanes can be prepared efficiently by making use of self-assembly processes between the precursors. These interactions are still present in the final product and, as a consequence, only a discrete number of low energy conformations and co-conformations are possible and the interconversion processes are well defined.

Figure 8 shows the eight possible supramolecular dynamic processes that take place in a [2]catenane with two stations. The NMR characterization of the different processes has been addressed by dynamic NMR methods using derivatives of lower symmetry, e.g., by introducing elements of planar chirality in the spacers X1, X2, A1 or A2.

The conceptually simplest dynamic process in rotaxanes is the translation of the ring along the axle, although additional motions of the cyclic component – analogous to those observed in catenanes – are also observed (Figure 9).

Polyrotaxanes contain several threaded macrocycles. In pseudo-polyrotaxanes, there are no steric barriers to prevent dethreading and the macrocyclic components can equilibrate with the free form. However, macrocycles cannot pass each other on their way to the end of the linear chain and dethreading.

Pseudo-polyrotaxanes display complex dynamic processes involving interference between translational motion, dethreading and steric effects between different macrocycles threaded by the same linear component. These specific supermolecular dynamic problems give rise to unusual dynamic NMR situations. The NMR spectra of a system formed by a polymeric thread, alternating electron rich 1,5-dioxonaphthalene and 1,4-dioxobenzene, and an electron-poor cyclophane displays two sets of signals in slow exchange.³³ However, the site-hopping rate was independently determined to be fast in the NMR

Process	Rotation of ...	Through/Around ...
1	Crown ether	Cyclophane
2	Cyclophane	Crown ether
3	A1 ring	O-----O axis
4	A2 ring	O-----O axis
5	X1 ring	C-----C axis
6	X2 ring	C-----C axis
7	Bipyridinium	N-----N axis
8	Crown ether, Cyclophane	Dihedral axis defined by the two mean planes

chemical shift time scale. The two signals arise from fast average between different populations: one of them comprises the free form and those macrocycles that can escape rapidly from the thread. The second population includes all macrocyclic rings that exchange slowly with the free form because of the presence of another ring along the thread that prevents them from reaching the end of the polymer. The ‘membership’ in one of the two populations is therefore defined by the fulfillment or not of the fast exchange condition with the free form. At constant temperature, the population of each site depends on the observation frequency and therefore the average chemical shift that characterizes each site is also field dependent.

3.3 Dynamics of Guests: Guest Exchange

NMR methods are well suited to study the kinetics of exchange of small guests in and out of the cavities determined by their hosts. Exhaustive recompilations of kinetic and thermodynamic data for macrocyclic hosts and a variety of guests have been published.^{34–36}

Exchange contributes to line broadening by modulating the chemical shift or the quadrupolar interaction in the guest. In the well-studied alkali metal ions, quadrupolar relaxation is usually substantially enhanced in the complexes because of their lower symmetry, compared with the solvated species. On the other hand, the alkali metal chemical shift differences between the complexed and solvated forms are smaller than the line-widths and the signals overlap.

The lifetime of the solvated state, τ_a , in the intermediate exchange regime is given by

$$\frac{1}{\tau_a} = (R_{av} - P_a R_a - P_b R_{obs}) \frac{(R_{obs} - R_a)}{(R_{av} - R_{obs})} \quad (10)$$

where P_a and R_a are the population and transverse relaxation rate of the solvated ion in the absence of exchange and P_b , R_b are the corresponding values for the complexed form. R_{obs} is the observed transverse relaxation rate and $R_{av} = P_a R_a + P_b R_b$.³⁷

When the relaxation rates of the complexed and free forms are comparable, i.e., $(\omega_a - \omega_b)^2 \gg (R_a - R_b)^2$, the exchange contribution to transverse relaxation provides an estimation

of the exchange lifetime, τ , which has contributions from the lifetimes of both the solvated and the complexed forms, through

$$\frac{1}{\tau} = \frac{1}{\tau_a} + \frac{1}{\tau_b} = P_a P_b (\omega_a - \omega_b)^2 R_{ex}^{-1} \quad (11)$$

In the slow exchange regime, separate signals are observed and exchange rates can be obtained by EXSY or 1D magnetization transfer experiments.

3.4 Dynamic Coupling between Host and Guest

The mobility of guests molecules is restricted to different degrees by their hosts. Kitzinger et al.³⁸ suggested that the dynamic coupling between molecular motions of the components should be one of the three defining parameters for supramolecular complexes, in addition to their thermodynamic stability and dissociation kinetics.

Dynamic coupling coefficient in the nano-picosecond time scale is defined as the ratio of the correlation times of the host and the guest. Correlation times are derived from heteronuclear NMR relaxation rate measurements. Size and shape matching and the existence of multiple specific binding points between host and guest have a strong influence in the dynamic coupling between host and guest.

Signal splitting in a symmetrical host may also be caused by the inclusion of a low symmetry guest that undergoes restricted reorientation inside the host's cavity. This is the case of a D_2 symmetrical tetrameric capsule that can accommodate large hosts. When the host is 2-adamantanone, the symmetry of the complex is reduced from D_2 to C_2 and signal splitting is observed (analogous to situation 2(a) in Box 1). On the other hand, with 2,6-adamantanedione the D_2 symmetry is maintained and no signal splitting is observed (Figure 10).³⁹

Restricted reorientation of an asymmetric guest can also cause the appearance of isomeric complexes (cf. situation 3(b))

Figure 10 Symmetry reduction by the enclosed guest. The structure shown in (a) can form a large tetrameric capsule. When $R' \neq H$ the capsule has no symmetry planes. Inclusion of adamantanone leads to signal splitting as the ‘top’ and ‘bottom’ parts of the capsule become non-equivalent. This is not observed when the guest is more symmetrical

of Box 1). Carcerands formed by linking two different bowl-shaped molecules and containing a low symmetry guest can exist as a mixture of two carceplexes that differ only by the orientation of the guest inside the cavity. These isomers have been called 'carceromers'.⁴⁰

Guest molecules trapped inside cavities may show different conformational preferences and different activation energies to the interconversion between isomers. The inversion of six member ring systems (cyclohexane, 1,4-dioxane, 1,4-thioxane, fluorocyclohexane, chlorocyclohexane, bromocyclohexane) have been measured in different supramolecular complexes, either in solution or in the solid state as urea inclusion compounds.

Interestingly, the increase in the interconversion barriers, if it exists, is small and seems to depend more on specific interactions between host and guest than on steric hindrance by the host walls. In particular, the inversion of 1,4-dioxane and 1,4-thioxane in a covalently linked carcerand or in a structurally related non-covalent capsule have the same barriers.⁴¹ Also, the inversion barrier of fluorocyclohexane in solution is identical, within experimental error, to that measured in solid thiourea-fluorocyclohexane inclusion compounds by three different techniques: line shape analysis, $T_{1\rho}$ measurement and selective polarization inversion. On the other hand, substantial differences are observed in the rate of rotation of the amide bond in dimethylformamide or dimethylacetamide in carceplexes and are interpreted as a combination of steric and solvation effects.

3.5 Solid State NMR Studies of Guest Reorientation

Solid state NMR techniques can be applied to the study of the motions of guest inside host's cavities. Two types of supramolecular systems can be considered. On the one hand, there are 'molecular' host-guest systems that can exist as discrete entities in solution. On the other hand guests can be included in cavities that only exist in a crystalline arrangement of the host and, therefore, can only be studied in the solid-state.

Solid state studies are useful for 'molecular' host-guest systems, as the mobility of the host is strongly restricted. In addition, NMR can be used to differentiate static from dynamic disorder in X-ray structures.⁴²

Solid hosts can have cavities of different sizes and topology, including linear channels, cages, networks and planes. Hosts can be inorganic, such as aluminosilicates (zeolites and clay materials) or organic solids, such as urea, and thiourea. See **Inclusion Compounds**.

²H-NMR is the method of choice to study guest mobility in the solid state. ²H-NMR is dominated by the nuclear quadrupole coupling. This arises from the interaction of the nuclear quadrupole moment with the electric field gradient, a tensorial quantity. For deuterium ($I = 1$) quadrupole coupling gives rise to two lines. A powder line shape is obtained by the summation of the contributions of randomly oriented crystallites. Pairs of singularities (edges, shoulders and peaks) in the spectrum are separated by frequencies that are proportional to the magnitudes of the principal values of the effective quadrupole coupling tensor. Reorientation of the guest at intermediate rates ($>10^4 \text{ s}^{-1}$) changes the ²H-NMR line shape. By comparison with simulations, specific motional models can be proved. In the fast motion limit ($>10^7 \text{ s}^{-1}$) the line shape corresponds to an average effective tensor, which is obtained by

adding the weighted contributions from all the sites visited during the motion.

Dynamic information can equally be obtained from the averaging of other tensorial quantities such as the shielding tensors.

Under cross-polarization magic angle spinning conditions (CP-MAS) indications about mobility can be obtained from the averaging of dipolar interactions. Rigid C-H fragments, with large dipolar couplings, show strong signal attenuation by dipolar dephasing when a short delay is introduced before acquisition.⁴³ Mobile C-H fragments show enhanced sensitivity, due to the NOE, under pulse saturation techniques.⁴⁴

4 CONCLUDING REMARKS

Dynamic processes are inherent to species stabilized by non-covalent bonds and changes in experimental conditions may cause substantial changes in the geometry or the nature of supramolecular species. The relative dynamics of guest and host can also have a substantial effect on the spectroscopic and chemical properties of supramolecular inclusion compounds. NMR spectroscopy is unique among the spectroscopic and analytical tools in its capability to capture the complex static and dynamic stereochemistry properties of supramolecular complexes. In these efforts, the design and study of species of reduced symmetry is often an essential part in the characterization of supramolecular systems. Spectroscopic, stereochemical and synthetic chemical knowledge have to be integrated.

In the rapidly evolving field of supramolecular chemistry, NMR is expected to keep playing a central role, but supramolecular chemistry is also expected to contribute to the development of NMR techniques. This is especially evident in the light of the renewed interest in liquid crystalline systems, in the use of paramagnetic tags to induce orientation in proteins, the use of micellar systems to reduce the correlation times of large molecules by using low viscosity solvents, or the screening of ligand libraries. All these are basically supramolecular phenomena that forecast an even stronger connection between supramolecular chemistry and NMR.

1 INTRODUCTION

Thioredoxins and glutaredoxins are ubiquitous small proteins involved in redox reactions in cells and viruses, including ribonucleotide reduction, sulfate metabolism, and both oxidative and reductive thiol–disulfide reactions with proteins.^{1,2} Recent work implicates thioredoxin in cellular redox control mechanisms and also in mammalian virus systems, with possible applications in therapeutics.³ The active sites of thioredoxin and glutaredoxin are similar, consisting of two cysteine (Cys) residues which are separated by two other residues and which are present as a disulfide in the oxidized protein and as a dithiol in the reduced protein. The active-site sequence in thioredoxin is -Cys-Gly-Pro-Cys- (where Gly = glycine, Pro = proline) and in glutaredoxin is -Cys-Pro-Tyr-Cys- (where Tyr = tyrosine).²

NMR spectra of *Escherichia coli* thioredoxin were reported as early as 1976,⁴ but extensive NMR studies on these proteins were not made until the advent of high-field spectrometers in the 1980s. The NMR spectrum of a protein gives information on the three-dimensional (3D) structure (see *Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*). Structure determination has provided a major impetus in the study of thioredoxins and glutaredoxins by NMR, since, with the exception of the well-known X-ray crystal structure of the oxidized form of *E. coli* thioredoxin,⁵ X-ray crystallography could not be used to derive structures because crystals were not formed. Oxidized *E. coli* thioredoxin was crystallized in the presence of Cu²⁺,⁶ crystals of reduced *E. coli* thioredoxin have not been found under the same conditions due to the redox reaction between the copper ions and the protein dithiol. Its 3D structure has therefore been solved by NMR spectroscopy,⁷ and a recent high-resolution structure determination by NMR for both oxidized and reduced *E. coli* thioredoxin⁸ has allowed direct comparison of the two forms of the protein under identical conditions.

The structure of reduced human thioredoxin cloned from T-lymphocytes and overexpressed in *E. coli* has also been solved by NMR,⁹ and the structures of both oxidized and reduced forms of a mutant protein have recently been published.¹⁰ Although the glutaredoxin from T4 bacteriophage

has been crystallized and its structure determined by X-ray crystallography,¹¹ *E. coli* glutaredoxin has not been crystallized; the structures of both oxidized and reduced glutaredoxin have recently been determined by NMR.^{12,13}

The NMR spectrum of a protein also gives a great deal of useful site-specific information, and can be used to probe enzyme mechanism and function and ligand binding. A number of such studies have been performed for thioredoxins and glutaredoxins and are summarized in this article, together with work on the structures of these proteins.

2 NMR OF *ESCHERICHIA COLI* THIOREDOXIN

2.1 Solution Conditions for NMR

The stability and small size of *E. coli* thioredoxin (108 amino acids, M_r 11 700) make it a suitable candidate for NMR spectroscopy. Both the oxidized and reduced forms are soluble to approximately 4 mM at pH 5.7 in 100 mM phosphate buffer^{4,14} and to 5–8 mM in 150 mM NaCl/20 mM phosphate, pH 5.7.¹⁵ Dithiothreitol (DTT)-free reduced thioredoxin is prepared from the oxidized form of the protein by the addition of DTT and subsequent passage of the solution through a short column of Sephadex G25 equilibrated under argon.¹⁶ The NMR spectrum is well dispersed with narrow resonance lines under these conditions. At pH values below 5.5 broadening of resonances in the NMR spectrum is observed, indicating the onset of aggregation, which occurs as the pI (~ 4) is approached.⁴ The NMR spectrum as a whole is unaffected by pH changes up to pH 10, indicating that the structure of the protein is largely unaffected by pH in this range.¹⁷ Certain resonances shift with pH due to the titrations of the N-terminal amine, the single histidine residue, and a buried aspartate near the active site in both oxidized and reduced thioredoxins, and by the titrations of the two thiol groups in reduced thioredoxin.¹⁷

2.2 Resonance Assignments and Structure Determination

A number of methods have been used for resonance assignment of *E. coli* thioredoxin. Pioneering studies in the use of isotope labeling were performed with oxidized thioredoxin, including the development of random fractional deuteration as a means of spectrum simulation and stereospecific assignment,^{15,18,19} and specific labeling of amino acids as a means of sequential resonance assignment.^{20,21} Backbone and C- β ,H ¹H resonance assignments of the oxidized form of *E. coli* thioredoxin were largely completed using these methods combined with conventional ¹H two-dimensional (2D) spectroscopy.¹⁵ Proton-only 2D NMR was used to obtain complete ¹H assignments for both oxidized and reduced *E. coli* thioredoxin,¹⁶ and these assignments were used as a basis for the calculation of the solution structure of reduced *E. coli* thioredoxin using distance and dihedral angle restraints from ¹H 2D NOESY and COSY spectra.⁷ The NMR spectra of reduced and oxidized *E. coli* thioredoxin are very similar, differing only in the region of the active site,^{14,16} and the NMR solution structure of reduced thioredoxin is virtually identical to the X-ray crystal structure of oxidized thioredoxin.⁵ Even

in the active site region where the NMR spectra of the two forms are different, the backbone conformations of the two forms of the protein are superimposable, and there are only the most subtle differences in the disposition of the side chains in this region. A total of 853 interresidue and 391 intraresidue distance constraints and 43 dihedral angle constraints were used in the calculation of the structure using the program DISGEO, and the resulting structures were refined with molecular dynamics (AMBER), for a final average rms deviation from the average structure of 0.564 for backbone heavy atoms of residues 3–108.⁷

The NMR solution structure of reduced *E. coli* thioredoxin represents probably one of the largest that has been calculated using ¹H 2D methods alone. Resonance overlap and the resulting ambiguities in estimates of internuclear distance lower the number of available distance and dihedral angle restraints, and hence the potential resolution of the structure. The additional resolution provided by the use of protein uniformly labeled with ¹³C and ¹⁵N^{22,23} allows the addition of a significantly greater number of restraints to the calculation, resulting in a higher resolution structure. High-resolution structures have recently been calculated, using the program DIANA followed by refinement with molecular dynamics (AMBER), for both oxidized and reduced *E. coli* thioredoxin⁸ using 2846 (reduced) and 2710 (oxidized) NOE distance restraints from 3D ¹³C and ¹⁵N heteronuclear NOESY spectra and 131 (reduced) and 136 (oxidized) dihedral angle restraints obtained from coupling constants. Final backbone average rms deviations from the average structure of 0.29 Å and 0.35 Å were obtained for the well-defined residues (4–107) of 30 reduced and oxidized thioredoxin structures respectively.⁸ A superposition of 20 of each of the calculated structures is shown in Figure 1.

2.3 Nitrogen-15 Relaxation and Polypeptide Backbone Dynamics

The backbone and tryptophan side-chain dynamics of oxidized and reduced thioredoxin have been estimated using uniformly ¹⁵N-labeled protein,²⁴ and show a number of regions, especially in turns and loops, where backbone flexibility is high compared with that of the polypeptide present in ordered secondary structure. The rather low proportion of flexible regions in thioredoxin is consistent with the exceptionally high thermal stability of this protein in either oxidation state.²⁵ The active site loop is also apparently flexible, but measurements are hampered because the sequence contains Gly and Pro, for which the ¹⁵N relaxation parameters are not measurable. Differences in the flexibility of loops adjacent to the active site occur between the oxidized and reduced forms of the protein (see Section 2.5).

2.4 pH-Dependence of the Mechanism of Thioredoxin Dithiol–Disulfide Exchange

The mechanism of reduction by thioredoxin is thought to proceed via nucleophilic attack by a thiolate anion belonging to Cys-32, with formation of a mixed disulfide.²⁶ Control of the pH in the active site region is therefore likely to be crucial to the reaction. The pK_a for deprotonation of Cys-32 was shown in chemical modification studies to be considerably lowered from normal, to a value of about 6.7,²⁶ consistent with its postulated role as primary nucleophile. However, the mechanism is apparently quite complex, as shown by an NMR study of reduced and oxidized thioredoxin as a function of pH between 5.7 and 10.¹⁷ pK_a values of 7.1 and 8.4 were obtained

Figure 1 Stereo view showing the best-fit superposition for residues 4–107 of 20 NMR solution structures of reduced *E. coli* thioredoxin (yellow) and oxidized thioredoxin (blue) obtained using the distance geometry program DIANA followed by molecular dynamics refinement with AMBER. The active site (residues 32–35) is at the bottom right of the structure. (Reproduced by permission from Jeng et al.⁸)

for two groups titrating in the active site region of reduced thioredoxin, consistent with the values previously obtained for the two active site thiols.²⁶ However, a third group also titrates in the active site region, giving a pK_a of 7.5 in oxidized thioredoxin and ~ 7.1 in reduced thioredoxin. Mutant studies by NMR²⁷ and other methods^{28,29} indicate that this titrating group is most likely the buried carboxyl group of aspartic acid (Asp)-26, which is thus revealed as an important factor in the pH control of the mechanism of *E. coli* thioredoxin.

2.5 Structural and Functional Differences between Oxidized and Reduced Thioredoxin
